Notice

Medical knowledge is constantly changing. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the publisher nor the author assume any liability for any injury and/or damage to persons or property arising from this publication.

Contributors

SHIZUO AKIRA MD, PhD

Director, Akira Innate Immunity Project
Exploratory Research for Advanced Technology (ERATO)
Japan Science Technology Agency (JST);
Professor, Department of Host Defense
Research Institute for Microbial Diseases
Osaka University
Osaka
Japan

JUAN ANGUIA PhD

Assistant Professor
Veterinary and Animal Sciences
University of Massachusetts
Amherst, MA
USA

GREGORY M. ANSTEAD MD, PhD

Director, Immunosuppression Clinic
South Texas Veterans Healthcare System;
Assistant Professor, Department of Medicine
Division of Infectious Diseases
University of Texas Health Science Center at San Antonio
San Antonio, TX
USA

CYNTHIA ARANOW MD

Associate Professor
Center of Autoimmune Disease
The Feinstein Institute for Medical Research
Manhasset, NY
USA

HOWARD A. AUSTIN III MD

Clinical Investigator
Clinical Research Center
National Institute of Diabetes and Digestive and Kidney Diseases
National Institutes of Health
Bethesda, MD
USA

SUBASH BABU MBS, PhD

Staff Scientist, Helminth Immunology Section
Laboratory of Parasitic Diseases
National Institute of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, MD
USA

JAMES R. BAKER JR MD

Division Chief, Allergy and Clinical Immunology
Department of Internal Medicine;
Director, The MI Nanotechnology Institute for Medicine
and Biological Sciences
Ann Arbor, MI
USA

CHRISTOPHER S. BALIGA MD

Resident, Department of Medicine
University Hospitals of Cleveland
Case Western Reserve University
Cleveland, OH
USA

MARK BALLOW MD

Chief, Division of Allergy and Immunology
Department of Pediatrics SUNY Buffalo School of Medicine
Women and Children's Hospital of Buffalo
Buffalo, NY
USA

JAMES E. BALOW MD

Clinical Director
Clinical Research Center; Kidney Disease Section
National Institute of Diabetes and Digestive and Kidney Diseases
National Institutes of Health
Bethesda, MD
USA

EMIL J. BARDANA JR MD, CM

Professor of Medicine
Division of Allergy and Clinical Immunology
Oregon Health and Science University
Portland, OR
USA

MATTHIAS D. BECKER MD, PhD, FEBO

Professor of Ophthalmology
Interdisciplinary Uveitis Center
University of Heidelberg
Heidelberg
Germany

JOHN W. BELMONT MD, PhD

Professor
Department of Molecular and Human Genetics
Baylor College of Medicine
Houston, TX
USA

DINA BEN-YEHUDA MD

Head, Department of Hematology
Hadassah Hebrew University Medical Center
Jerusalem
Israel

CLAUDIA BEREK PhD

Senior Scientist
B Cell Immunology
Deutsches Rheuma-ForschungsZentrum (DRFZ)
Berlin
Germany

THOMAS BIEBER MD, PhD

Professor of Dermatology and Allergy
Chairman and Director
Department of Dermatology and Allergy
University of Bonn
Bonn
Germany

JOHANNES W.J. BIJLSMA MD, PhD

Rheumatologist
Professor and Head
Department of Rheumatology and Clinical Immunology
University Medical Center Utrecht
Utrecht
The Netherlands

JACK J.H. BLEESING MD, PhD

Attending Physician
Division of Hematology/Oncology
Cincinnati Children's Hospital Medical Center
Cincinnati, OH
USA

SARAH E. BLUTT PhD

Assistant Professor
Department of Molecular Virology and Microbiology
Baylor College of Medicine
One Baylor Plaza
Houston, TX
USA

ELENA BORZOVA MD, PhD

Clinical Research Fellow
Dermatology Centre
Norfolk and Norwich University Hospital
Norwich
UK

PROSPER N. BOYAKA PhD

Associate Professor
Department of Veterinary Biosciences
The Ohio State University
Columbus, OH
USA

KNUT BROCKOW MD

Dermatologist, Allergologist;
Senior Medical Staff; Lecturer
Department of Dermatology and Allergy Biederstein
Technical University Munich
Munich
Germany

RALPH C. BUDD MD

Director
Vermont Center for Immunology and Infectious Diseases;
Professor of Medicine
University of Vermont College of Medicine
Burlington, VT
USA

FRANK BUTTGEREIT MD

Deputy Clinical Director
Department of Rheumatology and Clinical Immunology
Charité University Hospital
CCM, Berlin
Germany

VIRGINIA L. CALDER PhD

Lecturer in Immunology
Institute of Ophthalmology
University College London
London
UK

FABIO CANDOTTI MD

Senior Investigator
Genetics and Molecular Biology Branch;
Head, Disorders of Immunity Section
National Human Genome Research Institute
National Institutes of Health
Bethesda, MD
USA

SEBASTIAN CAROTTA PhD

Erwin Schrödinger Fellow
Immunology Division
The Walter and Eliza Hall Institute of Medical Research
Parkville, Victoria
Australia

JEAN-LAURENT CASANOVA MD, PhD

Professor of Pediatrics
Laboratory of Human Genetics and Infectious Diseases
Faculty of Medicine
René Descartes University of Paris;
Department of Immunology and Paediatric Hematology
Necker Sick Children's Hospital
APHP
Paris
France

MARILIA CASCALHO MD, PhD

Assistant Professor
Departments of Surgery, Immunology and Pediatrics
Mayo Clinic
Rochester, MN
USA

EDWIN S.L. CHAN MD, FRCP

Assistant Professor
Department of Medicine
New York University School of Medicine
New York, NY
USA

JAVIER CHINEN MD, PhD

Assistant Professor
Department of Pediatrics
Allergy and Immunology Section
Baylor College of Medicine
Houston, TX
USA

MONIQUE E. CHO MD

Clinical Investigator
Kidney Disease Branch
National Institute of Diabetes and Digestive and Kidney Diseases
National Institutes of Health
Bethesda, MD
USA

LISA CHRISTOPHER-STINE MD, MPH

Co-Director
Johns Hopkins Myositis Center;
Assistant Professor, Division of Rheumatology
Department of Medicine
Johns Hopkins University School of Medicine
Baltimore, MD
USA

HELEN L. COLLINS PhD

Lecturer in Immunology
Division of Immunology
Infection and Inflammatory Diseases
Kings College London
London
UK

ANDREW P. COPE BSc, PhD, MBBS, FRCP, ILTM

Head of Molecular Medicine
Reader in Molecular Medicine;
Honorary Consultant in Rheumatology
The Kennedy Institute of Rheumatology
Faculty of Medicine
Imperial College London
London
UK

IRENE CORTESE MD

Clinical Fellow
Neuroimmunology Branch
National Institute of Neurological Disorders and Stroke
National Institutes of Health
Bethesda, MD
USA

BRUCE N. CRONSTEIN MD

Professor of Medicine, Pathology and Pharmacology
Department of Medicine (Clinical Pharmacology);
Department of Pathology and Pharmacology
New York University School of Medicine
New York, NY
USA

ADNAN CUSTOVIC MD, PhD

Professor of Allergy
University of Manchester
Manchester
UK

MARINOS C. DALAKAS MD

Chief, Neuromuscular Diseases Section
National Institutes of Health
Bethesda, MD
USA

BLYTHE H. DEVLIN PhD

Assistant Research Professor
Department of Pediatrics
Duke University Medical Center
Durham, NC
USA

BETTY DIAMOND MD

Chief, Center of Autoimmune Disease
The Feinstein Institute for Medical Research
Manhasset, NY
USA

ANGELA DISPENZIERI MD

Associate Professor of Medicine
Division of Hematology
Mayo Clinic
Rochester, MN
USA

JOOST P.H. DRENTH MD, PhD

Professor of Molecular Gastroenterology and Hepatology
Division of Gastroenterology and Hepatology
Department of Medicine
Radboud University Nijmegen Medical Center
Nijmegen
The Netherlands

TERRY W. DU CLOS MD, PhD

Professor, Department of Internal Medicine
University of New Mexico School of Medicine;
Chief of Rheumatology
Veteran's Administration Medical Center
Albuquerque, NM
USA

MARK S. DYKEWICZ MD, FACP, FAAAAI

Professor of Internal Medicine
Allergy and Immunology Program Director
Saint Louis University School of Medicine
St Louis, MO
USA

TODD N. EAGAR PhD

Assistant Professor
Department of Neurology and Department of Immunology
University of Texas Southwestern Medical School
Dallas, TX
USA

GEORGE S. EISENBARTH MD, PhD

Executive Director
Barbara Davis Center for Childhood Diabetes;
Professor of Pediatrics, Immunology and Medicine
University of Colorado Health Sciences Center
Aurora, CO
USA

CHARLES O. ELSON III MD

Professor of Medicine and Microbiology
University of Alabama at Birmingham
Birmingham, AL
USA

DORUK ERKAN MD

Associate Physician-Scientist
The Barbara Volcker Center for Women and Rheumatic Disease;
Assistant Attending Physician
Hospital for Special Surgery;
Assistant Professor of Medicine
Weill Medical College of Cornell University
New York, NY
USA

MARK FEINBERG MD, PhD

Vice President
Policy, Public Health and Medical Affairs
Merck Vaccines
West Point, PA
USA

EROL FIKRIG MD

Professor of Medicine, Microbial Pathogenesis
Epidemiology and Public Health
Section of Rheumatology
Department of Internal Medicine
Yale University School of Medicine
New Haven, CT
USA

ALAIN FISCHER MD, PhD

Professor of Pediatrics
Director of the Pediatric Immunology Department and INSERM
Laboratory 'Normal and Pathological Development of the Immune
System'
Feculté de médecine
René Descartes
Paris
France

THOMAS A. FLEISHER MD

Chief, Department of Laboratory Medicine
Chief, Immunology Service, DLM
NIH Clinical Center
National Institutes of Health
Bethesda, MD
USA

ANDREW P. FONTENOT MD

Henry N. Clamen Associate Professor
Department of Medicine
University of Colorado at Denver and Health Sciences Center
Denver, CO
USA

KAREN A. FORTNER PhD

Research Assistant Professor
Immunobiology Program
Department of Medicine
The University of Vermont College of Medicine
Burlington, VT
USA

ANTHONY J. FREW MD, FRCP

Professor of Allergy and Respiratory Medicine
Department of Respiratory Medicine
Brighton General Hospital
Brighton
UK

THEA M. FRIEDMAN PhD

Associate Scientist
Director, Laboratory Services
The Cancer Center
Hackensack University Medical Center
Hackensack, NJ
USA

KOHTARO FUJIIHASHI DDS, PhD

Professor, School of Dentistry;
Co-Director, Immunobiology Vaccine Center
The University of Alabama
Birmingham, AL
USA

STEPHEN J. GALLI MD

Mary Hewitt Loveless Professor
Professor of Pathology and of Microbiology and Immunology;
Chair, Department of Pathology
Stanford University School of Medicine
Stanford, CA
USA

MOSHE E. GATT MD

Fellow, Lecturer
Department of Hematology
Hadassah Hebrew University Medical Center
Jerusalem
Israel

M. ERIC GERSHWIN MD

Distinguished Professor of Medicine
The Jack and Donald Chia Professor
of Medicine;
Chief, Division of Rheumatology
Allergy and Clinical Immunology
Genome and Biomedical Sciences Facility
University of California at Davis
Davis, CA
USA

JÖRG J. GORONZY MD, PhD

Mason I. Lowance MD Professor of Medicine
Director, Kathleen B. and Mason I. Lowance Center for Human
Immunology
Department of Medicine
Emory University School of Medicine
Atlanta, GA
USA

CLIVE E.H. GRATTAN MD, FRCP

Consultant Dermatologist
Dermatology Centre
Norfolk and Norwich University Hospital
Norwich
UK

NEIL S. GREENSPAN MD, PhD

Professor, Department of Pathology
Case Western Reserve University
Cleveland, OH
USA

BEATRIX GRUBECK-LOEBENSTEIN MD

Director, Institute for Biomedical Aging Research
Austrian Academy of Sciences
Austria

GABRIELLE HAEBERLI MD

Senior Resident, Division of Allergology
Bern Ziegler Hospital
Bern
Switzerland

RUSSELL P. HALL III MD

J. Lamar Callaway Professor and Chief
Division of Dermatology
Department of Medicine;
Professor, Department of Immunology
Duke University Medical Center
Durham, NC
USA

ROBERT G. HAMILTON PhD, D.ABMLI

Professor of Medicine and Pathology
Johns Hopkins Asthma and Allergy Center
Johns Hopkins University School of Medicine
Baltimore, MD
USA

GREGORY R. HARRIMAN MD

Vice President, Research and Development
Therakos, Exton, PA
USA

KHALED M. HASSAN BA

BS Pre-Doctoral Research Fellow
Division of Dermatology
Department of Medicine
Duke University Medical Center
Durham, NC
USA

ARTHUR HELBLING MD, FAAAAI

Professor of Internal Medicine and Allergology
Department for Rheumatology and Clinical Immunology/
Allergology
Inselspital
University of Bern
Bern, Switzerland

DAVID B. HELLMANN MD, MACP

Vice Dean and Chairman
 Department of Medicine
 Johns Hopkins Bayview Medical Center;
 Aliko Perroti Professor of Medicine
 Johns Hopkins University School of Medicine
 Baltimore, MD
 USA

VIVIAN HERNANDEZ-TRUJILLO MD

Attending Physician
 Division of Allergy and Clinical Immunology
 Miami Children's Hospital
 Miami, FL
 USA

MELANIE HINGORANI MBBS, MD, FRCophth

Consultant Ophthalmologist
 Eye Department
 Hinchingsbrooke Hospital
 Huntingdon
 UK

STEVEN M. HOLLAND MD

Chief, Laboratory of Clinical Infectious Diseases
 National Institute of Allergy and Infectious Diseases
 National Institutes of Health
 Bethesda, MD
 USA

HENRY A. HOMBURGER MD

Professor of Laboratory Medicine
 Mayo College of Medicine;
 Consultant, Department of Laboratory Medicine and Pathology
 Mayo Clinic
 Rochester, MN
 USA

MCDONALD HORNE MD

Senior Clinical Investigator
 Hematology Service
 Department of Laboratory Medicine
 National Institutes of Health
 Clinical Center
 Bethesda, MD
 USA

GABOR ILLEI MD, PhD, MHS

Chief, Sjögrens Syndrome Clinic
 National Institute of Dental and Craniofacial Research
 National Institutes of Health
 Bethesda, MD
 USA

JOHN IMBODEN MD

Professor, Department of Medicine
 University of California
 San Francisco, CA
 USA

KEN J. ISHII MD, PhD

Group Leader, Akira Innate Immunity Project
 Exploratory Research for Advanced Technology (ERATO)
 Japan Science Technology Agency (JST);
 Associate Professor, Department of Protozoology
 Research Institute for Microbial Diseases
 Osaka University
 Osaka
 Japan

SHAI IZRAELI MD

Head, Research Section on Childhood Malignancies
 Cancer Research Center
 Sheba Medical Center
 Tel-Hashomer
 Ramat Gan
 Israel

ELAINE S. JAFFE MD

Chief, Hematopathology Section;
 Acting Chief, Laboratory of Pathology
 Center for Cancer Research, National Cancer Institute
 National Institutes of Health
 Bethesda, MD
 USA

SIRPA JALKANEN MD, PhD

Professor of Immunology
Director, MediCity Research Laboratory
University of Turku
Turku
Finland

CARL H. JUNE MD

Professor of Pathology Laboratory Medicine
Director of Translational Research Programs
Abramson Cancer Center
Philadelphia, PA
USA

BARRY D. KAHAN MD, PhD

Professor of Surgery
Director
Division of Immunology and Organ Transplantation
Department of Surgery
The University of Texas Medical School at Houston
Houston, TX
USA

AXEL KALLIES PhD

PhillipDesbrow Memorial Fellow
Immunology Division
The Walter and Eliza Hall Institute of Medical Research
Parkville, Victoria
Australia

STEFAN H.E. KAUFMANN PhD

Professor of Immunology and Microbiology
Director, Max-Planck-Institute for Infection Biology
Department of Immunology
Berlin
Germany

ARTHUR F. KAVANAUGH MD

Professor of Medicine
Center for Innovative Therapy
Division of Rheumatology, Allergy and Immunology
University of California at San Diego School of Medicine
La Jolla, CA
USA

GARY KORETZKY MD, PhD

Leonard Jarett Professor of Pathology Laboratory Medicine
Chief, Division of Rheumatology
Department of Medicine
University of Pennsylvania;
Investigator and Director
Signal Transduction Program
AFCRI
Philadelphia, PA
USA

ROBERT KORNGOLD PhD

Chief, Research Division
Cancer Center
Hackensack University Medical Center
Hackensack, NJ
USA

RANIA D. KOVAIOU PhD

Institute for Biomedical Aging Research
Austrian Academy of Sciences
Innsbruck
Austria

DOUGLAS B. KUHN PhD

Head, Neutrophil Monitoring Laboratory
Clinical Services Program
SAIC-Frederick, Inc.
NCI Frederick
Frederick, MD
USA

ROGER KURLANDER MD

Medical Officer
Hematology Section
Department of Laboratory Medicine
NIH Clinical Center
National Institutes of Health
Bethesda, MD
USA

ROBERT A. KYLE MD

Professor of Medicine
Laboratory of Medicine and Pathology
Mayo Clinic College of Medicine
Rochester, MN
USA

H. CLIFFORD LANE, MD

Chief, Clinical and Molecular Retrovirology Section
Laboratory of Immunoregulation
National Institute of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, MD
USA

ARIAN LAURENCE PhD, MRCP, MRCPPath

Visiting Postdoctoral Fellow
Molecular Immunology and Inflammation Branch
National Institute of Arthritis and Musculoskeletal and Skin
Diseases
National Institutes of Health
Bethesda, MD
USA

FRANÇOISE LE DEIST MD, PhD

Professor of Immunology
Department of Microbiology and Immunology
University of Montreal
Montreal, QC
Canada

SUSAN J. LEE MD

Assistant Professor
Division of Rheumatology, Allergy and Immunology
University of California at San Diego School
of Medicine
La Jolla, CA
USA

STEVEN J. LEMERY MD

Hematologist
Hematology Branch NHLBI
Department of Laboratory Medicine
National Institutes of Health
Clinical Center
Bethesda, MD
USA

MICHAEL J. LENARDO MD

Section Head
Molecular Development of the Immune System Section
Laboratory of Immunology
National Institute of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, MD
USA

ARNOLD I. LEVINSON MD

Professor of Medicine and Neurology
Chief, Allergy and Immunology Section
University of Pennsylvania School of Medicine;
Director, Penn Center for Clinical Immunology
Philadelphia, PA
USA

DAVID B. LEWIS MD

Professor and Member of the Program in Immunology
Department of Pediatrics
Stanford University School of Medicine;
Attending Physician at Lucile Salter Packard Children's
Hospital
Stanford, CA
USA

DOROTHY E. LEWIS PhD

Professor,
Internal Medicine, Microbiology & Immunology, and
Pathology
University of Texas Medical Branch
Galveston, TX
USA

JAY LIEBERMAN, MD

Resident Physician
Department of Internal Medicine
Washington University
St Louis, MO
USA

PHIL LIEBERMAN MD

Clinical Professor of Medicine and Pediatrics
University of Tennessee College of Medicine
Memphis, TN
USA

SUE L. LIGHTMAN PhD, FRCP, FRCOphth, FMedSci

Professor of Clinical Ophthalmology
Consultant Ophthalmologist
Department of Clinical Ophthalmology
Moorfields Eye Hospital
London
UK

MICHAEL D. LOCKSHIN MD, MACR

Director
Barbara Volcker Center for Women and Rheumatic Disease;
Co-Director, Mary Kirkland Center for Lupus Research
Hospital for Special Surgery;
Attending Physician, Hospital for Special Surgery;
Professor of Medicine and Obstetrics-Gynecology
Joan and Sanford Weill College of Medicine of Cornell University
New York, NY
USA

MICHAEL T. LOTZE MD

Professor of Surgery and Bioengineering
Vice Chair
Research
Department of Surgery;
Director
Strategic Partnerships
University of Pittsburgh Cancer Institute
University of Pittsburgh School of Medicine
Pittsburgh, PA
USA

MEGGAN MACKAY MD

Assistant Investigator
Autoimmune Disease Center
The Feinstein Institute for Medical Research
Manhasset, NY
USA

JONATHAN S. MALTZMAN MD, PhD

Assistant Professor
Renal-Electrolyte and Hypertension Division
Department of Medicine
University of Pennsylvania
Philadelphia, PA
USA

MICHAEL P. MANNS MD

Professor and Chairman
Department of Gastroenterology
Hepatology and Endocrinology
Hannover Medical School
Hannover
Germany

MARKUS Y. MAPARA MD, PhD

Associate Professor of Medicine
Scientific Director
Hematopoietic Stem Cell Transplantation Program
Division of Hematology/Oncology
University of Pittsburgh Cancer Institute
Pittsburgh, PA
USA

SUSANA MARINHO MD

Allergist Clinical Immunologist
Research Fellow
North West Lung Centre
Wythenshawe Hospital
University of Manchester
Manchester
UK

M. LOUISE MARKERT MD, PhD

Associate Professor of Pediatrics
Department of Pediatrics
Division of Allergy and Immunology
Duke University Medical Center
Durham, NC
USA

ALBERTO MARTINI MD

Professor and Head, Department of Pediatrics
University of Genoa and Istituto G. Gaslini
Genoa
Italy

SETH L. MASTERS PhD

Visting postdoctoral Fellow
Inflammatory Biology Section
National Institute of Arthritis and Musculoskeletal and
Skin Diseases
National Institutes of Health
Bethesda, MD
USA

EVELINA MAZZOLARI MD

Assistant Professor
Chief, Bone Marrow Transplantation Unit
Department of Pediatrics
University of Brescia
Italy

HENRY F. MCFARLAND MD

Chief, Neuroimmunology Branch
National Institute of Neurological Disorders and Stroke
National Institutes of Health
Bethesda, MD
USA

JERRY R. MCGHEE PhD

Adjunct Professor
Department of Microbiology
University of Alabama at Birmingham
Birmingham, AL
USA

FRANK MCKENNA BA, MD, FRCP

Consultant Physician and Rheumatologist
Rheumatic Diseases Unit
Trafford General Hospital
Manchester
UK

PETER C. MELBY MD

Professor, Department of Medicine
Division of Infectious Diseases
The University of Texas Health Science Center
San Antonio, TX
USA

DEAN D. METCALFE MD

Chief, Laboratory of Allergic Diseases
National Institute of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, MD
USA

MARTIN METZ MD

Post-Doctoral Scholar
Department of Pathology
Stanford University School of Medicine
Stanford, CA
USA

JOANN M. MICAN MD

Staff Clinician
Division of Clinical Research
National Institutes of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, MD
USA

STEPHEN D. MILLER, PhD

Congressman John E. Porter Professor
Director, Interdepartmental Immunobiology Center
Department of Microbiology-Immunology
Feinberg School of Medicine
Northwestern University Medical School
Chicago, IL
USA

CAROLYN MOLD PhD

Professor
Department of Molecular Genetics and Microbiology
University of New Mexico School of Medicine
Albuquerque, NM
USA

DAVID R. MOLLER MD

Associate Professor of Medicine
Department of Medicine
Johns Hopkins Bayview Medical Center
Johns Hopkins University School of Medicine
Baltimore, MD
USA

ANTHONY MONTANARO MD

Professor of Medicine
Head, Division of Allergy and Clinical Immunology
Oregon Health and Sciences University
Portland, OR
USA

SCOTT N. MUELLER PhD

Postdoctoral Fellow
Emory Vaccine Center and Department of Microbiology and Immunology
Emory University
Atlanta, GA
USA

ULRICH R. MÜLLER MD

Professor
Consultant
Spital Ziegler
Spital Netz Bern
Bern
Switzerland

PHILIP M. MURPHY MD

Chief, Laboratory of Molecular Immunology
National Institute of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, MD
USA

PIERRE NOEL MD

Chief, Hematology Service
Department of Laboratory Medicine
National Institutes of Health
Clinical Center
Bethesda, MD
USA

LUIGI D. NOTARANGELO MD

Professor of Pediatrics and Pathology
Harvard Medical School;
Director of Research and Molecular Diagnosis Program on Primary
Immunodeficiencies
Division of Immunology
Children's Hospital
Boston, MA
USA

THOMAS B. NUTMAN MD

Head, Helminth Immunology Section;
Head, Clinical Parasitology Unit
Laboratory of Parasitic Diseases
National Institutes of Health
Bethesda, MD
USA

STEPHEN L. NUTT PhD

Pfizer Australia Research Fellow
Immunology Division
The Walter and Eliza Hall Institute of Medical Research
Parkville, Victoria
Australia

JOÃO BOSCO DE OLIVEIRA MD

Staff Scientist
Molecular Immunology and Genetics Section
Laboratory of Medical Investigation 56
University of São Paulo-USP
São Paulo
Brazil

STEPHEN N. OLIVER, MD

Assistant Professor
Department of Medicine
Division of Clinical Pharmacology
New York University School of Medicine
New York, NY
USA

CHRIS M. OLSON JR.

Graduate Student
Department of Veterinary and Animal Sciences
University of Massachusetts at Amherst
Amherst, MA
USA

JOHN O'SHEA MD

Chief, Molecular Immunology and Inflammation Branch;
Chief, Lymphocyte Cell Biology Section;
Scientific Director, Intramural Research Program
National Institute of Arthritis and Musculoskeletal and Skin
Diseases
National Institutes of Health
Bethesda, MD
USA

MARY E. PAUL MD

Associate Professor
Pediatric Allergy and Immunology
Baylor College of Medicine
Texas Children's Hospital
Houston, TX
USA

ERIK J. PETERSON MD

Assistant Professor
Department of Medicine
Division of Rheumatic and Autoimmune Diseases
Center for Immunology
University of Minnesota
Minneapolis, MN
USA

CAPUCINE PICARD, MD, PhD

Immunologist and Paediatrician
 Director of Immunodeficiencies Study Center
 Necker Sick Children's Hospital
 APHP;
 Laboratory of Human Genetics and Infectious Diseases
 Faculty of Medicine
 René Descartes University of Paris
 Paris
 France

WERNER J. PICHLER MD

Head of Allergology
 Department for Rheumatology and Clinical Immunology/
 Allergology
 Inselspital
 University of Bern
 Bern
 Switzerland

STANLEY R. PILLEMER MD

Vice President
 Clinical Research and Product Safety Macrogenics
 Rockville, MD
 USA

STEFANIA PITTALUGA MD, PhD

Staff Physician
 Laboratory of Pathology
 National Cancer Institute
 National Institutes of Health
 Hematopathology Section
 Bethesda, MD
 USA

JEFFREY L. PLATT MD

Director, Transplantation Biology;
 Professor of Surgery
 Immunology and Pediatrics
 Mayo Clinic
 Rochester, MN
 USA

PAUL H. PLOTZ MD

Chief, Arthritis and Rheumatism Branch
 National Institute of Arthritis and Musculoskeletal and Skin
 Diseases
 National Institutes of Health
 Bethesda, MD
 USA

ANDREAS RADBRUCH PhD

Scientific Director
 Deutsches Rheuma-Forschungszentrum (DRFZ)
 Berlin
 Germany

ANGELO RAVELLI MD

Associate Professor
 Department of Pediatrics
 University of Genoa and Istituto G. Gaslini
 Genoa
 Italy

JOHN D. REVEILLE MD, FACP

Professor
 Director, Division of Rheumatology
 The University of Texas Health Sciences Center at Houston
 Houston, TX
 USA

ROBERT R. RICH MD

Senior Vice President
 Dean of School of Medicine;
 Professor of Medicine and Microbiology
 University of Alabama at Birmingham
 Birmingham, AL
 USA

MARGARET E. RICK MD

Assistant Chief, Hematology Service
 Department of Laboratory Medicine
 National Institutes of Health
 Clinical Center
 Bethesda, MD
 USA

KIMBERLY A. RISMA MD, PhD

Assistant Professor of Pediatrics
 Division of Allergy/Immunology
 Cincinnati Children's Hospital Medical Center
 Cincinnati, OH
 USA

JOHN R. RODGERS PhD

Assistant Professor
 Department of Immunology
 Baylor College of Medicine
 Houston, TX
 USA

ANTONY ROSEN, MD

Mary Betty Stevens Professor of Medicine
Professor of Medicine and Pathology;
Director, Division of Rheumatology
Johns Hopkins University School of Medicine
Baltimore, MD
USA

JAMES T. ROSENBAUM MD

Edward E. Rosenbaum Professor of Inflammation Research
Departments of Ophthalmology
Medicine and Cell Biology
Oregon Health and Science University
Portland, OR
USA

MARC E. ROTHENBERG MD, PhD

Director Endowed Chair
Division of Allergy and Immunology;
Professor of Pediatrics
Cincinnati Children's Hospital Medical Center
University of Cincinnati College of Medicine
Cincinnati, OH
USA

BARRY T. ROUSE DVM, DSc

Distinguished Professor
Department of Pathobiology
College of Veterinary Medicine
University of Tennessee
Knoxville, TN
USA

SCOTT ROWLEY MD

Division Chief, Blood and Marrow Stem Cell Transplantation
The Cancer Center
Hackensack University Medical Center
Hackensack, NJ;
Clinical Associate Professor
University of Medicine and Dentistry of New Jersey
Newark, NJ
USA

MARTINA RUDELIUS MD

Postdoctoral Research Fellow
National Cancer Institute
National Institutes of Health
Bethesda, MD
USA

SHIMON SAKAGUCHI, MD, PhD

Professor and Chair
Department of Experimental Pathology
Institute for Frontier Medical Sciences
Kyoto University
Kyoto
Japan

MARKO SALMI MD, PhD

Director of Laboratory
Department of Bacterial and Inflammatory Diseases
National Public Health Institute
MediCity Research Laboratory
University of Turku
Turku
Finland

ULRICH E. SCHAIBLE PhD

Professor of Immunology
Chair, Department of Infectious and Tropical Diseases
London School of Hygiene and Tropical Medicine
London
UK

HARRY W. SCHROEDER JR, MD, PhD

Professor, Departments of Medicine, Microbiology
and Genetics
University of Alabama at Birmingham
Birmingham, AL
USA

MARVIN I. SCHWARZ MD

James C. Campbell Professor of Medicine
University of Colorado at Denver and Health Sciences
Center
Denver, CO
USA

MARKUS J.H. SEIBEL MD, PhD, FRACP, FGABJS

Professor and Chair of Endocrinology
The University of Sydney;
Head, Bone Research Program
ANZAC Res Inst;
Director, Department of Endocrinology and Metabolism
Concord Hospital Medical Center
Concord, NSW
Australia

CARLO SELMI, MD

Assistant Professor of Medicine
 Division of Rheumatology
 Allergy and Clinical Immunology
 University of California at Davis
 Davis, CA
 USA;
 Division of Internal Medicine and Liver Unit
 San Paolo School of Medicine
 University of Milan
 Milan
 Italy

WILLIAM M. SHAFER PhD

Senior Research Career Scientist
 VA Medical Research Service;
 Professor of Microbiology and Immunology
 Department of Microbiology and Immunology
 Emory University School of Medicine
 Atlanta, GA
 USA

PREDIMAN K. SHAH MD

Director, Division of Cardiology
 Cedars-Sinai Medical Center
 Los Angeles, CA
 USA

MARYAM SHAHBAZ-SAMAVI MD, MRCP

Specialist Registrar in Rheumatology
 Rheumatology Department
 North Manchester General Hospital

Preface

TO THE FIRST EDITION

Clinical immunology is a discipline with a distinguished history, rooted in the prevention and treatment of infectious diseases in the late nineteenth and early twentieth centuries. The conquest of historical scourges such as smallpox and (substantially) polio and relegation of several other diseases to the category of medical curiosities is often regarded as the most important achievement of medical science of the past fifty years. Nevertheless, the challenges facing immunologists in the efforts to control infectious diseases remain formidable; HIV infection, malaria and tuberculosis are but three examples of diseases of global import that elude control despite major commitments of monetary and intellectual resources.

Although firmly grounded in the study and application of defenses to microbial infection, since the 1960s clinical immunology has emerged as a far broader discipline. Dysfunction of the immune system has been increasingly recognized as a pathogenic mechanism that can lead to an array of specific diseases and failure of virtually every organ system. Paradoxically, although the importance of the immune system in disease pathogenesis is generally appreciated, the place of clinical immunology as a practice discipline has been less clear. As most of the non-infectious diseases if the human immune system lead eventually to failure of other organs, it has been organ-specific subspecialists who have usually dealt with their consequences. Recently, however, the outlook has begun to change as new diagnostic tools increasingly allow the theoretical possibility of intervention much earlier in disease processes, often before irreversible target organ destruction occurs. More importantly, this theoretical possibility is increasingly realized as clinical immunologists find themselves in the vanguard of translating molecular medicine from laboratory bench to patient bedside.

In many settings, clinical immunologists today function as primary care physicians in the management of patients with immune-deficiency, allergic, and autoimmune diseases. Indeed many influential voices in the clinical disciplines of allergy and rheumatology support increasing coalescence of these traditional subspecialties around their intellectual core of immunology. In addition to his or her role as a primary care physician, the clinical immunologist is increasingly being looked to as a consultant, as scientific and clinical advances enhance his or her expertise. The immunologist with a 'generalist' perspective can be particularly helpful in the application of unifying principles of diagnosis and treatment across the broad spectrum of immunologic diseases.

Clinical Immunology: Principles and Practice has emerged from this concept of the clinical immunologist as both primary care physician and expert consultant in the management of patients with immunologic diseases. It opens in full appreciation of the critical role of fundamental immunology in this rapidly evolving clinical discipline. Authors of basic science chapters were asked, however, to cast their subjects in a context of clinical relevance. We believe the result is a well-balanced exposition of basic immunology for the clinician.

The initial two sections on basic principles of immunology are followed by two sections that focus in detail on the role of the immune system in defenses against infectious organisms. The approach is two-pronged. It begins first with a systematic survey of immune responses to pathogenic agents followed by a detailed treatment of immunologic deficiency syndromes. Pathogenic mechanisms of both congenital and acquired immune deficiency diseases are discussed, as are the infectious complications that characterize these diseases. Befitting its importance, the subject of HIV infection and AIDS receives particular attention, with separate chapters on the problem of infection in the immunocompromised host, HIV infection in children, anti-retroviral therapy and current progress in the development of HIV vaccines.

The classic allergic diseases are the most common immunologic diseases in the population, ranging from atopic disease to drug allergy to organ-specific allergic disease (e.g., of the lungs, eye and skin). They constitute a foundation for the practice of clinical immunology, particularly for those physicians with a practice orientation defined by formal subspecialty training in allergy and immunology. A major section is consequently devoted to these diseases, with an emphasis on pathophysiology as the basis for rational management.

The next two sections deal separately with systemic and organ-specific immunologic diseases. The diseases considered in the first of these sections are generally regarded as the core practice of the clinical immunologist with subdisciplinary emphasis in rheumatology. The second section considers diseases of specific organ failure as consequences of immunologically mediated processes that may involve virtually any organ system. These diseases include as typical examples the demyelinating diseases, insulin-dependent diabetes mellitus, the glomerulonephritides and inflammatory bowel diseases. It is in management of such diseases that the discipline of clinical immunology will have an increasing role as efforts focus on intervention early in the pathogenic process and involve diagnostic and therapeutic tools of ever-increasing sophistication. One of the major clinical areas in which the expertise of a clinical immunologist is most frequently sought is that of allogeneic organ transplantation. A full section is devoted to the issue of transplantation of solid organs, with an introductory chapter on general principles of transplantation and management of transplantation rejection followed by separate chapters dealing with the special problems of transplantation of specific organs or organ systems.

Appreciation of both the molecular and clinical features of lymphoid malignancies is important to the clinical immunologist regardless of subspecialty background, notwithstanding the fact that primary responsibility for management of such patients will generally fall to the haematologist/oncologist. A separate section is consequently devoted to the lymphocytic leukemias and lymphomas that constitute the majority of malignancies seen in the context of a clinical immunology practice. The separate issues of immune responses to tumors and immunological strategies to treatment of malignant diseases are subjects of additional chapters.

Another important feature is the attention to therapy of immunologic diseases. This theme is constant throughout the chapters on the allergic and immunologic diseases, and because of the importance the editors attach to clinical immunology as a therapeutic discipline, an extensive section is also devoted specifically to this subject. Subsections are devoted to issues of immunologic reconstitution, with three chapters on treatment of immunodeficiencies, malignancies and metabolic diseases by bone marrow transplantation. Also included is a series of chapters on pharmaceutical agents currently available to clinical immunologists, both as anti-allergic and anti-inflammatory drugs, as well as newer agents with greater specificity for T cell-mediated immune responses. The section concludes with a series of chapters that address established and potential applications of therapeutic agents and approaches that are largely based on the new techniques of molecular medicine. In addition to pharmaceutical agents the section deals in detail with such subjects as apheresis, cytokines, monoclonal antibodies and immunotoxins, gene therapy and new experimental approaches to the treatment of autoimmunity.

The book concludes with a section devoted to approaches and specific techniques involved in the diagnosis of immunologic diseases. Use of the diagnostic laboratory in evaluation of complex problems of immunopathogenesis has been a hallmark of the clinical immunologist since inception of the discipline and many clinical immunologists serve as directors of diagnostic immunology laboratories. Critical assessment of the utilization of techniques ranging from lymphocyte cloning to flow cytometric phenotyping to molecular diagnostics are certain to continue as an important function of the clinical immunologist, particularly in his or her role as expert consultant.

In summary, we have intended to provide the reader with a comprehensive and authoritative treatise on the broad subject of clinical immunology, with particular emphasis on the diagnosis and treatment of immunological diseases. It is anticipated that the book will be used most frequently by the physician specialist practicing clinical immunology, both in his or her role as a primary physician and as a subsequent consultant. It is hoped, however, that the book will also be of considerable utility to the non-immunologist. Many of the diseases discussed authoritatively in the book are diseases commonly encountered by the generalist physician. Indeed, as noted, because clinical immunology involves diseases of virtually all organ systems, competence in the diagnosis and management of immunological diseases is important to virtually all clinicians. The editors would be particularly pleased to see the book among the references readily available to the practicing internist, pediatrician and family physician.

Preface

TO THE THIRD EDITION

In the 12 years since publication of the first edition of *Clinical Immunology* much has changed; as we have increasingly appreciated the nature of the molecular mechanisms underlying inflammatory responses to specific antigens, the discipline has surely become more complex, more interesting and more demanding of its practitioners. Acquired immunity, the specialized development of vertebrate host defenses, was for many decades the primary focus of attention. Recently, however, we have witnessed an explosion of information relating to the phylogenetically older systems of innate immunity, which has concurrently enlarged the purview of clinical immunology. In addition to those classical diseases of the acquired immune system, clinical immunologists today are increasingly interested in a range of inflammatory diseases where rearranged antigen-specific receptors have not been demonstrated or may not be involved. Rather than specific antigen receptors, these disorders are mediated by pathogen-recognition systems such as Toll-like receptors on NK lymphocytes and phagocytic cells. These trigger inflammatory effector processes that were later adopted by the acquired immune system, such as elaboration of soluble inflammatory mediators (cytokines and chemokines), complement activation, phagolysosome-mediated pathogen elimination and programmed cell death.

The third edition reflects this improved understanding with increased attention to processes and diseases of inflammation and a broadly defined view of host defenses. We trust that this has been accomplished while retaining a principal focus on those many diseases at the core of clinical immunology arising from deficiency or aberration of functions of acquired immunity.

Two changes will be immediately apparent to readers familiar with the previous editions. The third edition is, we believe, much enhanced by production in full color throughout. Clinical case photos are increased and are presented more usefully in the context of text discussion. Similarly line drawings are not only more attractive, but utilize color effectively to enrich their information content. The second obvious change is that we have chosen to publish the book in a single (albeit large) volume rather than in the previous two-volume format. We believe that by editing to reduce redundancy, judicious referencing (with an emphasis on recent reviews) and tightening presentation, the third edition is consequently more “user friendly,” eliminating the necessity to consult more than a single volume, while not compromising overall content quality or quantity. There is also a third important change that is not immediately obvious, but which will considerably enhance the long-term usefulness of the book. This third change is the intent to provide quarterly electronic updates to registered purchasers relating to key advances in clinical immunology since the publication of this edition. We are confident that such updates will help to keep the book fresh as our field advances.

The process of editing a book of this size represents the combined efforts of many individuals in addition to the editors and authors. Two persons, however, warrant special thanks for their essential roles in shepherding this work to its conclusion: Martin Mellor and Randell Baker, whose efforts on behalf of the editors, authors and, finally, the readers, is gratefully acknowledged.

We trust that the book continues to find a useful place on the desks and book shelves of clinical immunologists of many stripes—from the specialized practitioner of clinical immunology (either generalized or organ-system oriented), to the generalist or organ-based specialist who is interested in state-of-the-art approaches to management of inflammatory conditions, and to the fundamental immunologist interested in

mechanisms of immunologic diseases. Finally, upon reviewing this comprehensive text on clinical immunology, which delves into the many and increasingly diverse areas of immune system related diseases, the editors hope that this recording of the expanse and depth of knowledge in our specialty will impart a sense of pride and possession to those clinicians and researchers who call themselves clinical immunologists.

Table of Contents

Pt. 1 Fundamental Principles of the Immune Response

1 The human immune response	3
2 Organization of the immune system	17
3 Innate immunity	39
4 Antigen receptor genes, gene products, and co-receptors	53
5 The major histocompatibility complex	79
6 Antigens and antigen processing	91
7 Antigen-presenting cells and antigen presentation	103
8 B-cell development and differentiation	113
9 T-cell development	127
10 Cytokines and cytokine receptors	139
11 Chemokines and chemokine receptors	173
12 Lymphocyte adhesion and trafficking	197
13 T-cell activation and tolerance	211
14 Programmed cell death in lymphocytes	225

Pt. 2 Host Defense Mechanisms and Inflammation

15 Immunoglobulin function	237
16 Regulatory T cells	249
17 Helper T-cell subsets and control of the inflammatory response	259
18 Cytotoxic lymphocyte function and natural killer cells	271
19 Host defenses at mucosal surfaces	287
20 Complement and complement deficiencies	305

Pt. 3 Infection and Immunity

21 Phagocyte deficiencies	327
22 Mast cells, basophils and mastocytosis	345
23 Eosinophils and eosinophilia	361
24 Immune response to extracellular bacteria	377
25 Immune responses to intracellular bacteria	389
26 Immune responses to spirochetes	411
27 Immune responses to viruses	421
28 Immune responses to protozoans	433
29 Immune responses to helminths	447

Pt. 4 Immunologic Deficiencies

30 Evaluation of the immunodeficient patient	463
31 Infections in the immunocompromised host	477

32 Development of the fetal and neonatal immune system	493
33 Aging and the immune system	503
34 Primary antibody deficiencies	513
35 Primary T-cell immunodeficiencies	531
36 Inherited disorders of IFN- γ -, IFN-[alpha]/[beta]-, and NF-kB-mediated immunity	553
37 HIV infection and acquired immunodeficiency syndrome	561
38 Immunodeficiency due to congenital, metabolic, infectious, surgical, and environmental factors	585

Pt. 5 Allergic Diseases

39 Pathogenesis of asthma	597
40 Management of the asthmatic patient	607
41 Rhinitis and sinusitis	627
42 Urticaria, angioedema, and anaphylaxis	641
43 Allergic reactions to stinging and biting insects	657
44 Atopic and contact dermatitis	667
45 Food allergy	681
46 Eosinophil-associated gastrointestinal disorders (EGID)	691
47 Allergic disorders of the eye	701
48 Drug hypersensitivity	709
49 Occupational and environmental allergic disorders	725

Pt. 6 Systemic Immune Diseases

50 Mechanisms of autoimmunity	739
51 Systemic lupus erythematosus	749
52 Rheumatoid arthritis	767
53 Juvenile idiopathic arthritis	789
54 Sjogren's syndrome	803
55 Systemic sclerosis	813
56 Inflammatory muscle diseases	825
57 Spondyloarthritis	837
58 Small- and medium-vessel primary vasculitis	859
59 Large-vessel vasculitides	885
60 Autoinflammatory fever syndromes	889
61 Antiphospholipid syndrome	909

Pt. 7 Organ Specific Inflammatory Disease

62 Immunohematologic disorders	921
63 Bullous diseases of the skin and mucous membranes	935
64 Myasthenia gravis	951

65 Multiple sclerosis	963
66 Autoimmune peripheral neuropathies	977
67 Immunologic renal diseases	995
68 Inflammation and atherothrombosis	1013
69 Autoimmune thyroid diseases	1023
70 Diabetes and related autoimmune diseases	1035
71 Immunologic lung diseases	1053
72 Sarcoidosis	1073
73 Immunologic ocular disease	1085
74 Immunologic disease of the gastrointestinal tract	1099
75 Inflammatory hepatobiliary cirrhosis	1115

Pt. 8 Neoplasia and the Immune System

76 Lymphoid leukemias	1131
77 Lymphomas including Hodgkin lymphoma	1151
78 Monoclonal gammopathies	1167
79 Tumor immunology and immunotherapy	1181

Pt. 9 Transplantation

80 Concepts and challenges in transplantation: rejection, immunosuppression and tolerance	1199
81 Challenges and potentials of xenotransplantation	1215
82 Hematopoietic stem cell transplantation for malignant diseases	1223
83 Stem cell transplantation and immune reconstitution in immunodeficiency	1237
84 Thymic reconstitution	1253

Pt. 10 Prevention and Therapy of Immunologic Diseases

85 Immunoglobulin therapy: replacement and immunomodulation	1265
86 Gene transfer therapy of immunologic diseases	1281
87 Glucocorticoids	1293
88 Nonsteroidal anti-inflammatory drugs	1307
89 Antihistamines	1317
90 Immunomodulating pharmaceuticals	1331
91 Protein kinase antagonists as therapeutic agents for immunological and inflammatory disorders	1341
92 Vaccines	1353
93 Immunotherapy of allergic disease	1383
94 Cytokine therapy	1393
95 Monoclonal antibodies and fusion proteins	1405

Pt. II Diagnostic Immunology

96 Assessment of proteins of the immune system	1419
97 Flow cytometry	1435
98 Assessment of functional immune responses	1447
99 Assessment of neutrophil function	1461
100 Assessment of human allergic diseases	1471
101 Molecular methods	1485

Appendices

1 Selected CD molecules and their characteristics	1505
2 Laboratory reference values	1513
3 Chemokines	1517
4 Cytokines	1521
Index	1527

The human immune response

Robert R. Rich

1

Arguably, clinical immunology touches as many organs and diseases as any other subspecialty of medicine. Indeed when ‘innate’ and ‘acquired’ immune mechanisms are both considered it would likely be possible to write a textbook relating to the immunologic diseases of virtually any organ system. The challenge for clinical immunologists is to reduce a dizzying array of disease descriptions, with increasingly defined cellular and molecular mechanisms, to a far more limited and systematic approach to disease management or, ideally, prevention. For the nonimmunologist, either generalist or specialist, the immunological forest is more important than the trees to the management of a specific patient with an immune disease. The role of a consulting immunologist is to bring understanding in depth of immune pathogenesis to bear in a particular patient setting.

This chapter is directed as a consult from a clinical immunologist to the generalist physician. It is predicated on the notion that appreciation of fundamental aspects of immune responses will facilitate understanding of immunologic diseases. The chapter is structured as an introduction to the interacting elements of the human immune system and their disordered functions in diseases. The subtleties are described in detail in the chapters that follow.

■ THE HOST–MICROBE INTERACTION ■

The vertebrate immune system is a product of eons of evolutionary struggle between rapidly evolving microbial pathogens and their much less rapidly reproducing, and hence less adaptable, hosts.¹ Unable to win the battle with microbial invaders by rapid mutation and selection, the immune system employs a strategy of complexity and redundancy involving both the individual organism and its population. Microbes respond by adaptations to particular elements of the immune system that they can turn to their own advantage. Reflecting plasticity of the response, specific defenses differ substantially based upon the nature of the infecting organism and its point of entry and distribution within the body. Regardless of the defense mechanism, an intended outcome is the destruction or neutralization of the invading organism. A secondary

consequence, however, can be collateral damage to host cells. These cells can be involved in the attack either as sites of microbial residence or as ‘innocent bystanders.’ Depending on the site and severity of the host defense response, it may be accompanied by local and/or systemic symptoms and signs of inflammation.

ACQUIRED AND INNATE IMMUNITY

Immune responses are traditionally classified as acquired (or specific) and innate (or nonspecific) (Table 1.1). The acquired immune system, present uniquely in vertebrates, is specialized for development of an inflammatory response based on recognition of specific ‘foreign’ macromolecules that are predominantly, but not exclusively, proteins or peptides. Its primary actors are antibodies, T lymphocytes, B lymphocytes, and antigen-presenting cells (APCs).

Innate immune responses are far more ancient, being widely represented in multicellular phyla.^{2,3} Rather than being based upon specific recognition of an exceedingly diverse array of macromolecules (i.e., antigens), it is focused on recognition of common molecular signatures of potential pathogens.^{4,5} For responses of both types, effector mechanisms can be based upon elaboration of soluble products acting systemically (humoral immunity) or can require direct cell-to-cell contact or the activity of cytokines and chemokines acting in the cellular microenvironment (cell-mediated immunity).

The elements of innate immunity are diverse. They include physical barriers to pathogen invasion (such as skin, mucous membranes, cilia, and mucus), as well as an array of cellular and serum factors that can be activated by secreted or cell surface products of the pathogen. Consequent activation of these cells induces an inflammatory response that uses mechanisms which are broadly shared with those of the specific immune system. Among these are natural killer (NK) cell-mediated cytotoxicity, activation of phagocytic cells, the secretion of inflammatory cytokines and chemokines, and the actions of the many participants in the complement cascade.

There is substantial overlap and redundancy between the innate and acquired immune systems. The distinguishing feature of the latter is the direct activation by antigen of lymphocyte clones with specific antigen

Table 1.1 Features of innate and acquired immune systems

<i>Distinguishing features</i>	
Innate immunity	Acquired immunity
Receptors fixed and based on pathogen molecular patterns Does not require immunization Little or no memory Includes physical barriers to pathogen	Receptors clonally variable and based on gene rearrangement Consequence of B- and/or T-cell activation Immunologic memory Antibody and cytotoxic T cells
<i>Common features</i>	
Cytokines and chemokines Complement cascade Phagocytic cells Natural killer (NK) cells Natural autoantibodies	

receptors. In contrast, innate immune responses are independent of the function of cells expressing such clonotypic receptors. Because recognition of pathogens by the innate immune system relies on germline-encoded cellular receptors and does not require clonal expansion of cells with receptors that are products of gene rearrangements, innate immunity is more rapidly responsive. It can initiate in minutes to hours and generally precedes development of a primary acquired immune response by at least several days. However, for the same reason, it does not exhibit specific memory for previous encounter with a particular pathogen.

helminths (Chapter 29). Their defensive functions are based not on phagocytic capabilities, but rather on their ability to discharge potent biological mediators into the cellular microenvironment. This process of degranulation can be triggered by antigen-specific IgE molecules bound to basophils and mast cells, which express high-affinity receptors for the Fc portion of IgE (FcεR on their surfaces). In addition to providing a mechanism for helminthic host defenses, this pathologic process is also the principal mechanism involved in acute (IgE-mediated) allergic reactions.

CELLS OF THE IMMUNE SYSTEM

The major cellular constituents of both innate and acquired immunity originate in the bone marrow where they differentiate from multipotential hematopoietic stem cells along several pathways to become granulocytes, lymphocytes, and APCs (Chapter 2).

GRANULOCYTES

Polymorphonuclear leukocytes (granulocytes) are classified by light microscopy into three types. By far the most abundant in the peripheral circulation are neutrophils, which are principal effectors of antibody and complement-mediated immune responses (Chapter 21). They are phagocytic cells that ingest, kill, and degrade phagocytosed microbes and other targets of an immune attack within specialized cytoplasmic vacuoles. Phagocytic activity of neutrophils is promoted by their surface display of receptors for antibody molecules (specifically the Fc portion of immunoglobulin G (IgG) molecules) and complement proteins (particularly the C3b component). Neutrophils are the predominant cell type in acute inflammatory infiltrates and are the primary effector cells in immune responses to pyogenic organisms (Chapter 24).

Eosinophils (Chapter 23) and basophils (Chapter 22) are the other circulating forms of granulocytes. A close relative of the basophil, but derived from distinct bone marrow precursors, is the tissue mast cell that does not circulate in the blood. Eosinophils, basophils, and mast cells are important in host defenses to multicellular pathogens, particularly

LYMPHOCYTES

Three types of lymphocytes are identified based on display of particular surface molecules: B cells, T cells, and NK cells. All lymphocytes differentiate from common lymphoid stem cells in the bone marrow. T cells undergo further maturation and selection in the thymus for expression of antigen receptors useful in self/nonself discrimination (Chapter 9). B cells continue differentiation into antibody-producing cells in the bone marrow (Chapter 8).

T cells and B cells are the heart of specific immune recognition, a property reflecting their clonally specific cell surface receptors for antigen (Chapter 4). B-cell receptors for antigen (BCR) are membrane immunoglobulin (mIg) molecules of the same antigenic specificity that the cell and its terminally differentiated progeny, plasma cells, will secrete as soluble antibodies. The T-cell receptor for antigen (TCR) is a heterodimeric integral membrane molecule expressed exclusively by T lymphocytes.

Receptors for “antigen” on the third class of lymphocytes, NK cells, are not clonally expressed. Expressing receptors, however, for moieties that can be regarded as molecular signatures of pathogens, NK cells serve as major constituents of innate immunity. They also recognize target cells that might otherwise elude the immune system (Chapter 18). NK cell differentiation is particularly driven by interleukin (IL)-15. Recognition of NK cell targets is based largely on what their targets lack rather than on what they express. NK cells express receptors of several types for major histocompatibility complex (MHC) class I molecules via killer cell

immunoglobulin-like receptors (KIR).⁶ KIR can either inhibit or activate NK cell activity utilizing receptors for MHC class I molecules or other immune adaptor molecules that express a tyrosine-based inhibitory-motif (ITIM) or tyrosine-based activation motif, respectively, in their intracellular domain. NK cells will kill target cells unless they receive an inhibitory signal transmitted by an ITIM receptor. Because virus-infected cells and tumor cells may attempt to escape T-cell recognition by downregulating their expression of class I molecules, such cells can become susceptible to NK cell-mediated killing.

NK cells can also participate in antigen-specific immune responses by virtue of their surface display of the activating ITAM receptor CD16, which binds the constant (Fc) region of IgG molecules. This enables them to function as effectors of a cytolytic mechanism termed antibody-dependent cellular cytotoxicity (ADCC).⁷

In general, pathways leading to differentiation of T cells, B cells, and NK cells are mutually exclusive, representing a permanent lineage commitment. No lymphocytes express both mIg and TCR. Some T cells, however, also display NK cell surface markers, including MHC class I receptors, and exhibit both NK-like cytotoxicity and antigen-specific T-cell responsiveness.

Antigen-presenting cells

A morphologically and functionally diverse group of cells, all of which are derived from bone marrow precursors, is specialized for presentation of antigen to lymphocytes, particularly T cells (Chapter 7). Included among such cells are monocytes (present in the peripheral circulation); macrophages (solid tissue derivatives of monocytes); cells resident within the solid organs of the immune system such as dendritic cells; and constituents of the reticular endothelial system within other solid organs. B lymphocytes that specifically capture antigen by virtue of mIg receptors can also function efficiently in antigen presentation to T cells.

Cardinal features of APCs include their expression of both class I and class II MHC molecules (the latter can either be expressed constitutively or can be induced by cytokines) as well as requisite accessory molecules for T-cell activation (e.g., B7-1, B7-2/CD80, CD86).⁸ Upon activation, APCs also elaborate cytokines that induce specific functions in cells to which they are presenting antigen.

APCs differ substantially among themselves with respect to mechanisms of antigen uptake and effector functions. Monocytes and macrophages are actively phagocytic, particularly for antibody and/or complement-coated (opsonized) antigens that bind to their surface receptors for Fc γ and C3b. These cells are also important effectors of

immune responses, especially in sites of chronic inflammation. Upon further activation by T-cell cytokines, they can kill ingested microorganisms by oxidative pathways similar to those employed by polymorphonuclear leukocytes. In addition, they can kill adjacent target cells by a cytotoxic mechanism. Mature dendritic cells, although efficient in antigen presentation and T-cell activation, have little phagocytic function and are not known to participate as effectors in immune responses. Immature dendritic cells, however, phagocytose apoptotic cells and present antigenic peptides from such cells to T lymphocytes.

The interaction between B cells acting as APCs and T lymphocytes is particularly interesting as the cells are involved in a mutually amplifying circuitry of antigen presentation and response. The process is initiated by antigen capture through B-cell mIg and ingestion by receptor-mediated endocytosis. This is followed by antigen degradation and then display to T cells as oligopeptides bound to MHC molecules. In addition, like other APCs, B cells display CD80, thereby providing a requisite second signal to the antigen-responsive T cell via its accessory molecule for activation, CD28⁸ (Fig. 1.1). As a result of T-cell activation, T-cell cytokines that regulate B-cell differentiation and antibody production are produced and T cells are stimulated to display the surface ligand CD40L (CD154) that can serve as the second signal for B-cell activation through its inducible surface molecule CD40.

BASIS OF ACQUIRED IMMUNITY

The essence of acquired immunity is molecular distinction between self constituents and potential pathogens (for simplicity, self/nonself discrimination). This discrimination is predominantly a responsibility of T lymphocytes. It reflects the selection of thymocytes that have generated specific antigen receptors, and that upon later encounter can bind both self MHC molecules and nonself antigenic peptides. The consequence of this selection process is that foreign proteins are recognized as antigens but self proteins are tolerated (i.e., are not perceived as antigens).

T lymphocytes generally recognize antigens as a complex of short linear peptides bound to MHC molecules on the surfaces of APCs (Chapter 7). With the exception noted below, T cells do not bind antigen in native conformation. Furthermore, they do not recognize antigen in solution. The vast majority of antigens for T cells are oligopeptides, although utilizing specialized antigen-presenting molecules, T cells can also recognize other molecular species such as glycolipids. Antigen recognition by T cells differs fundamentally, however, from that by antibodies, which are produced by B lymphocytes and their derivatives. Antibodies, unlike T cells, can bind complex macromolecules and can bind them either at cell surfaces or in solution. Moreover, antibodies show less preference for recognition of proteins; antibodies against carbohydrates, nucleic acids, lipids, and simple chemical moieties can be readily produced. Although B cells can also be rendered unresponsive by exposure to self-antigens, particularly during differentiation in the bone marrow, this process does not define foreignness within the context of self-MHC recognition.

CLONAL BASIS OF IMMUNOLOGICAL MEMORY

An essential element of self/nonself discrimination is the clonal nature of antigen recognition. Although the immune system can recognize a vast array of distinct antigens, all of the receptors of a single T cell or B cell

KEY CONCEPTS

Fig. 1.1 Antigen-binding molecules. Antigen-binding pockets of immunoglobulin (Ig) and T-cell receptor (TCR) are comprised of variable segments of two chains translated from transcripts that represent random V(D)J or VJ gene segment rearrangements. Antigen-binding grooves of major histocompatibility complex (MHC) molecules are formed with contributions of α_1 and β_1 domains of class II molecules and α_1 and α_2 domains of class I molecules. In contrast to Ig and TCR, MHC binding sites do not reflect genetic rearrangements. All of these molecules are members of the immunoglobulin superfamily. HLA, human leukocyte antigen; mIgM, membrane immunoglobulin M.

(and their clonal progeny) have identical antigen-binding sites and hence a particular specificity. A direct consequence is the capacity for antigen-driven immunologic memory. This phenomenon derives from the fact that, after an initial encounter with antigen, clones of lymphocytes of appropriate specificity proliferate, resulting in a greater and more rapid response upon subsequent antigen encounter. These two hallmarks of the specific immune system, clonal specificity and immunological memory, provide a conceptual foundation for the use of vaccines in prevention of infectious diseases (Chapter 92). Immunologic memory involves not only the T cells charged with antigen recognition, but also the T cells and B cells that mediate the efferent limb of an inflammatory response. In its attack on foreign targets, the immune system may display exquisite specificity for the inducing antigen, as is seen in the lysis of virus-infected target cells by cytolytic T cells. However, an immunologic attack *in vivo* will also have important elements that are independent of antigen recognition, such as the response of phagocytes to inflammatory mediators.

MECHANISMS OF IMMUNOLOGIC DISEASES

The pathogenic pathways that lead to diseases of the immune system are based on an understanding of its physiology and its perturbations in disease states (Table 1.2). First, immunologic disease can reflect a failure or deficiency of the immune system (Chapters 30–38). This pathway is similar to that accounting for most diseases of other organ systems, i.e., a consequence of failure of physiologic function. Considering the essential role of the immune system in defenses against microbes, such failures are usually identified by increased susceptibility to infection (Chapter 31). Failure can be congenital (e.g., X-linked agammaglobulinemia) or acquired (e.g., acquired immunodeficiency syndrome (AIDS)). It can be global (e.g., severe combined immunodeficiency) or quite specific, involving only a particular component of the immune system (e.g., selective IgA deficiency).

A second mechanism, malignant transformation (Chapters 76–78), is also common to virtually all organ systems. Malignancies of the

5. Untoward consequences of physiologic immune function

hematopoietic system are familiar to all physicians. Manifestations of these diseases are protean, most commonly reflecting the secondary consequences of solid-organ or bone marrow infiltration and immune system deficiency.

Dysregulation of an essentially intact immune system provides a third pathway to immune pathogenesis. Features of an optimal immune response include antigen recognition and elimination with little adverse effect on the host. Both initiation and termination of the response, however, involve regulatory interactions that can go awry when challenged by antigens of a particular structure or in a particular mode of presentation. Diseases of immune dysregulation reflect genetic and environmental factors that act together to subvert a normal immune response to some pathological end. The acute allergic diseases (Chapters 39–49) are examples of such disorders.

The fourth and fifth pathways to immunopathogenesis are more specific to the immune system. The fourth lies at the heart of specific immune system function, i.e., the molecular discrimination between self and nonself. Ambiguity in this discrimination can lead to autoimmune tissue damage (Chapters 50–75). Although such damage can be mediated by either antibodies or T cells, the frequent association of particular diseases with inheritance of specific human leukocyte antigen (HLA)

alleles (Chapter 5) suggests that the pathogenesis of autoimmune diseases usually represents a failure of self/nonself discrimination by T cells. This failure to discriminate can be general, leading to development of systemic autoimmune diseases such as systemic lupus erythematosus, or local, as in the organ-specific autoimmune diseases. In the latter instance, attack is directed against specific cells and usually particular cell surface molecules. In most cases, pathology is a consequence of target tissue destruction (e.g., multiple sclerosis, rheumatoid arthritis, insulin-dependent diabetes mellitus). However, it can also reflect hormone receptor blockade (e.g., myasthenia gravis, insulin-resistant diabetes) or hormone receptor stimulation (e.g., Graves' disease). It is thought that ambiguity in self/nonself discrimination is commonly triggered by an unresolved encounter with an infectious organism or other environmental agent, although this remains a subject of controversy⁹ (Chapter 50).

A fifth pathogenetic pathway to immunologic disease is disease development as a result of physiologic rather than pathologic function. Inflammatory lesions in such diseases are the result of the normal function of the immune system. A typical example is contact dermatitis to potent skin sensitizers such as urushiol, the causative agent of poison-ivy dermatitis (Chapter 44). These diseases can also have an iatrogenic etiology that can range from benign (e.g., delayed hypersensitivity skin test reactions) to life-threatening (e.g., graft-versus-host disease, organ graft rejection).

■ ANTIGEN-BINDING MOLECULES ■

Three sets of molecules are responsible for the specificity of acquired immune responses by virtue of their capacity to bind foreign antigen. These molecules are Ig, TCR, and MHC molecules (Fig. 1.1; Chapters 4 and 5). All are products of a very large family of ancestrally related genes, the immunoglobulin superfamily (IgSF).¹⁰ Members of the IgSF, which includes many other molecules essential to induction and regulation of immune responses, exhibit characteristic structural features. The most notable of these is organization into homologous domains of approximately 110 amino acids that are usually encoded by a single exon and characteristically have an intradomain disulfide bond. Typically, each domain assumes a configuration of anti-parallel strands that form two opposing β -pleated sheets.

KEY CONCEPTS

FEATURES OF THE IMMUNOGLOBULIN SUPERFAMILY

- >> Large family of ancestrally related genes (probably > 100 members)
- >> Most products involved in immune system function or other cell-cell interactions
- >> Proteins exhibit domain structure of ~100 amino acids, usually translated from a single exon and characteristically with a single intradomain disulfide bond
- >> Tertiary structure of protein typified by anti-parallel strands forming a pair of β -pleated sheets

IMMUNOGLOBULINS AND T-CELL RECEPTORS

The exquisite specificity of Ig and TCR molecules for antigen is achieved by a mechanism of genetic recombination that is unique to Ig and TCR genes (Chapter 4). The antigen-binding site of both types of molecules is comprised of a groove formed by contributions from each of two constituent polypeptides. In the case of immunoglobulins, these are a heavy (H) chain and one of two alternative types of light (L) chains, κ or λ . In the case of TCR, either of two alternative heterodimers may constitute the antigen-binding molecule, one comprised of α and β chains, and the other of γ and δ chains. The polypeptides contributing to both Ig and TCR can be divided into an antigen-binding amino-terminal variable (V) domain and one or more carboxy-terminal constant (i.e., nonvariable) domains. Ig constant region domains generally include specific sites responsible for the biological effector functions and other activities of the molecule (Chapter 15).

The most noteworthy feature of the vertebrate immune system is the process of genetic recombination that generates a virtually limitless array of specific antigen receptors from a rather limited genomic investment. This phenomenon is accomplished by the recombination of genomic segments that encode the variable portions of Ig and TCR polypeptides¹¹ (Chapter 4). The products of these rearranged genes provide a specific B or T cell with its unique antigen receptor. The mature receptor consists

KEY CONCEPTS

COMPARISON OF T-CELL AND B-CELL RECEPTORS FOR ANTIGEN

Similarities

- >> Members of the immunoglobulin (Ig) superfamily
- >> Heterodimeric antigen-binding groove
- >> Divided into variable and constant regions
- >> Variable regions constructed by V(D)J rearrangements
- >> Nongenomic N-nucleotide additions at V(D)J junctions
- >> Exhibit allelic exclusion
- >> Mature T cells and B cells display receptors of one and only one antigenic specificity
- >> Negative selection for receptors with self-antigen specificity
- >> Transmembrane signaling involving co-receptor molecules

Differences

- >> Ig binds antigen in solution; T-cell receptor (TCR) binds antigen when presented by antigen-presenting cell
- >> Ig can be secreted; TCR is not
- >> Somatic hypermutation of Ig genes
- >> Isotype switching of Ig genes
- >> Inflammatory effector functions by the Ig constant domains
- >> Selection of TCR for self-major histocompatibility complex (MHC) recognition

of the products of two or three such rearranged segments. These are designated V (variable) and J (joining), for IgL chains and TCR α and γ chains, and V, D (diversity) and J, for IgH and TCR β and δ chains.

DNA rearrangement involved in generating T- and B-cell receptors is controlled by recombinases that are active in early thymocytes and in pro-B cells in the bone marrow. The process is sequential and carefully regulated, leading to translation of one receptor of unique specificity for any given T or B lymphocyte. This result is achieved through a process termed *allelic exclusion*, wherein only one member of a pair of allelic genes potentially contributing to an Ig or TCR molecule is rearranged at a time.¹² If a productive rearrangement is achieved, i.e., a full-length transcript that will encode the appropriate protein product, the other member of the allelic pair is permanently inactivated. If, on the other hand, the first effort at rearrangement is not productive, resulting in a truncated transcript, two alternatives are presented. The cell can attempt a second (or more) rearrangement at the same gene, depending upon the availability of unrearranged D and/or J segments. Alternatively, the process can move to the second member of the pair on the homologous chromosome, which will similarly undergo rearrangement. This affords a cell several opportunities to construct a variable region sequence that encodes a full-length receptor transcript. The frequency of nonproductive rearrangements is high because of a secondary mechanism that contributes substantially to potential receptor diversity. This process, termed N-nucleotide addition, results in the insertion at the time of rearrangement of one or more nongenic nucleotides at the junctions between V, D, and J segments.¹¹ A frequent consequence of this process is a codon frameshift and, hence, a nonproductive rearrangement.

In addition to the process of allelic exclusion, there are other control mechanisms to insure that a lymphocyte expresses a single antigen receptor. B cells exclusively rearrange Ig genes, but not TCR genes, and vice versa for T cells. Moreover, B cells sequentially rearrange L-chain genes, typically κ before γ . Thus, B cells express either κ or γ chains, but not both. Similarly, thymocytes express α and β genes or γ and δ genes, and, with the caveat that some V δ gene segments can rearrange with some Ja and vice versa, one never finds T cells with $\alpha\delta$ or $\gamma\beta$ receptors. Indeed, Va \rightarrow Ja rearrangement generally deletes the DJC δ locus that is embedded within the α gene complex. Interestingly, the TCR α gene complex and IgL chain genes can occasionally rearrange independent of the constraints of allelic exclusion.¹³ This allows possible expression of two different TCR α or IgL chains. However, only one of these is typically expressed by the cell – a process termed *phenotypic exclusion*.

There is one feature of V-region construction that is essentially reserved to B cells. This is *somatic hypermutation* (SHM), a process that can continue throughout the life of a mature B cell at the hypervariable sites of both the V_H and V_L genes.¹¹ The amino acid products of these sites, particularly at V, D, and J junctions, are the specific points of contact with antigen within the binding groove. As antigen is introduced into the system, mature B cells remain genetically responsive to the antigenic environment. As a consequence, through SHM of mIg, a few B cells increase their affinity for antigen. Such cells are preferentially activated, particularly at limiting doses of antigen. Thus, the average affinity of antibodies produced during the course of an immune response increases – a process termed affinity maturation. The process of SHM is not limited to V-region coding segments, but extends to 3' and 5' flanking sequences; indeed, the start of the hypermutation domain lies within the V-gene promoter. SHM is driven by an enzyme, activation-induced cytidine deaminase (AID), that catalyzes mutation of deoxycytidine to

deoxyuracil in single-stranded DNA.¹⁴ Inactivation of AID is associated with development of hyperIgM syndrome (Chapter 34). The process of SHM is also of pathogenetic importance in a variety of B-cell lymphomas and leukemias, and possibly in nonlymphoid malignancies as well.^{14,15}

The products of TCR genes generally do not show evidence of SHM. This virtual absence of hypermutation may be related to the fundamental responsibility of T cells for discrimination between self and nonself through a rigorous process of selection in the thymus that involves co-recognition of a self-MHC molecule and antigenic peptide¹⁶ (Chapter 9). This process results in deletion by apoptosis of the vast majority of differentiating thymocytes by mechanisms that place stringent boundaries around the viability of a thymocyte with a newly expressed TCR specificity. Once a T cell is fully mature and ready for emigration from the thymus, its TCR is essentially fixed, thus reducing the likelihood of emergent autoimmune T-cell clones in the periphery.

The receptor expressed by a developing thymocyte must be capable of binding with low-level affinity to some particular MHC self-molecule, either class I or class II, expressed by a resident thymic APC. If it does not exhibit such binding affinity, the TCR can make further attempts to construct an appropriate receptor by additional Va \rightarrow Ja rearrangements. If it is not ultimately successful, the developing thymocyte dies. Because their receptors are generated by a process of random gene rearrangement, most thymocytes fail this test. They are consequently deleted as not being useful to an immune system that requires T cells to recognize self-MHC molecules. Thymocytes surviving this hurdle are said to have been “positively selected”¹⁶ (Fig. 1.2A). Conversely, a small number of thymocytes bind with an unallowably high affinity for a combination of MHC molecule plus antigenic peptide expressed by a thymic APC. Because the peptides available for MHC binding at this site are derived almost entirely from self proteins, differentiating thymocytes with such receptors are intrinsically dangerous as potentially autoimmune. This deletion of thymocytes with high-affinity receptors for self-MHC plus (presumptively) self-peptide is termed “negative selection” (Fig. 1.2B), a process that may also involve activity of T-regulatory cells (Tregs).^{17,18}

Although not selected for recognition of foreignness in the context of self, maturing pre-B cells in the bone marrow are also subject to negative selection upon encounter with “self” soluble or particulate antigen, and B cells in peripheral tissues may be rescued by ligand engagement in a process resembling positive selection.^{19,20} Additionally, IgM-producing B cells with low-affinity specificity for autoantigens that are cross-reactive with bacterial glycoconjugates appear to be positively selected during B-cell development.²¹ Conversely, studies in transgenic mice suggest that when an initial pre-B-cell mIg is cross-linked by encounter of relatively high affinity with self-antigen in the bone marrow, secondary rearrangements can occur. This process, termed receptor editing, can thus generate a new receptor lacking self reactivity²² (Chapter 8).

Another feature that distinguishes B cells from T cells is that the cell surface antigen receptors of the former are secreted in large quantities as antibody molecules, the effector functions of which are carried out in solution or at the surfaces of other cells. Secretion is accomplished by alternative splicing of Ig transcripts to include or exclude a transmembrane segment of the Ig heavy chains.

In addition to synthesizing both membrane and secreted forms of immunoglobulins, B cells also undergo class switching. Antibody molecules are comprised of five major classes (isotypes). In order of abundance in the serum these are IgG, IgM, IgA, IgD, and IgE (Chapters 4 and 15). The IgG class is further subdivided into four

Fig. 1.2 Two-stage selection of thymocytes based on binding characteristics of randomly generated T-cell receptors (TCR). Panel A: Positive selection. “Double-positive” (CD4, CD8) thymocytes with TCR capable of low-affinity binding to some specific self-major histocompatibility complex (MHC) molecule (either class I or class II) expressed by thymic cortical epithelial cells are positively selected. This process may involve sequential attempts at a gene rearrangement in order to express an $\alpha\beta$ TCR of appropriate self-MHC specificity. Thymocytes that are unsuccessful in achieving such a receptor die by apoptosis. The solid diamond represents a self-peptide derived from hydrolysis of an autologous protein present in the thymic microenvironment or synthesized within the thymic antigen-presenting cell (APC) itself. Panel B: Negative selection. “Single-positive” (CD4 or CD8) thymocytes, positively selected in stage one, that display TCR with *high* affinity for the combination of self-MHC plus some self (autologous) peptide present in the thymus are negatively selected (i.e., die). Those few thymocytes that have survived both positive and negative selection emigrate as mature T cells to the secondary lymphoid tissues.

subclasses and the IgA class into two subclasses. The class of immunoglobulin is determined by the sequence of the constant region of its heavy chain (C_H). The isotype-determining exons are located downstream (3') of the heavy-chain variable (V_H) genes. Thus, an antibody-producing cell can change the class of antibody molecule that it synthesizes by utilization of different C_H genes without changing its unique antibody specificity. This process, termed class switch recombination, is regulated by cytokines and, like SHM, is accomplished through the action of activation-induced cytidine deaminase.^{11,23}

There is no process comparable to class switch recombination in T cells. The two types of TCR are products of four independent sets of V-region and C-region genes. A substantial majority of T cells express the $\alpha\beta$ TCR. A small number express $\gamma\delta$ TCR (usually 5% or less in peripheral blood). There is a higher representation of $\gamma\delta$ T cells in certain tissues, particularly those lining mucous membranes, where they may be specialized for recognition of heavily glycosylated peptides or nonpeptide antigens. Thymocytes are committed to the expression of either $\alpha\beta$ or $\gamma\delta$ TCR and their differentiated progeny (T cells) never undergo secondary changes in the periphery.

MAJOR HISTOCOMPATIBILITY COMPLEX

MHC molecules constitute a third class of antigen-binding molecules. When an MHC class I molecule was initially crystallized, an unknown peptide was found in a binding groove formed by the first two domains

(α_1 and α_2). This binding groove has since been established as a general feature of MHC molecules.²⁴ It is now known that the function of MHC molecules is to present antigen to T cells in the form of oligopeptides that reside within this antigen-binding groove. The most important difference between the nature of the binding groove of MHC molecules and those of Ig and TCR is that the former does not represent a consequence of gene rearrangement. Rather, all the available MHC molecules in an individual are encoded in a linked array within the MHC, which in humans is located on chromosome 6 and designated HLA (Chapter 5).

MHC molecules are of two basic types: class I and class II. Class I molecules have a single heavy chain that is an integral membrane protein comprised of three external domains (Fig. 1.1). The heavy chain is noncovalently associated with β_2 -microglobulin, a nonpolymorphic, nonmembrane-bound, single-domain molecule that is not encoded within the MHC (although it is a member of the IgSF). Class II MHC molecules, in contrast, are comprised of two polypeptide chains, α and β (or A and B), of approximately equal size, each of which consists of two external domains connected to a transmembrane region and cytoplasmic tail. Both chains of class II molecules are embedded within the cell membrane, and both are encoded within the MHC. Class I and class II molecules have a high degree of structural homology and both fold to form a peptide-binding groove on their exterior face, with contribution from the α_1 and α_2 domains for class I and from α_1 and β_1 domains for class II.²⁴ There are three class I loci (HLA-A, -B, and -C) and three

class II subregions (HLA-DR, -DQ, and -DP) that are principally involved in antigen presentation to T cells (Chapter 5). The functions of other class I and class II genes within this complex are less clear. Some at least appear to be specialized for binding (presentation) of peptide antigens of restricted type or source (e.g., HLA-E), and others are clearly involved in antigen processing (e.g., HLA-DM). Additionally, recent studies have established that members of a family of 'nonclassical' class Ib molecules, CD1_{a-d} which are encoded outside the MHC (on chromosome 1) are specialized for binding and presentation of lipid and lipid conjugate antigens to T cells.²⁵

The HLA complex represents an exceedingly polymorphic set of genes. Consequently, most individuals are heterozygous at each major locus, having inherited one allele from the father and an alternative at each locus from the mother. In contrast to TCR and Ig, the genes of the MHC are codominantly expressed, i.e., allelic exclusion does not operate on MHC genes. Thus, at a minimum, an APC can express six class I molecules and six class II molecules (the products of the two alternative alleles of three class I and three class II loci). This number is, in fact, usually an underestimate for two reasons. First, there may be products of other (nonclassical) MHC genes with specialized functions. Second, the class II loci are somewhat more complex than just suggested. For example, the DR β locus is duplicated so that most individuals express from each chromosome at least two different dimers, each comprised of a different β -chain joined to an identical nonpolymorphic α -chain. Additionally, because both the α and β loci for DQ are polymorphic and gene products can be assembled from *trans*-encoded transcripts, unique DQ $\alpha\beta$ combinations, not represented in *cis* by either parental chromosome, are possible. Class I genes are found on almost all somatic cells, whereas class II genes are restricted in expression primarily to cells specialized for APC function.

■ ANTIGEN PRESENTATION ■

Because MHC genes do not undergo recombination, the number of distinct antigen-binding grooves that they can form is many orders of magnitude less than that for either TCR or Ig. Oligopeptides that bind to MHC molecules are the hydrolytic products of self or foreign proteins. They are derived by hydrolytic cleavage within the APC and are loaded into MHC molecules before expression at the cell surface (Chapter 6). Indeed, stability of MHC molecules at the cell surface requires the presence of a peptide in the antigen-binding groove. Since most hydrolyzed proteins are of self origin, the binding groove of most MHC molecules contains a self peptide. Class I and class II molecules differ from one another in the length of peptides that they bind, usually 8–9 amino acids for class I and 14–22 amino acids for class II. Although important exceptions are clearly demonstrable, they also generally differ with respect to the source of peptide. Those peptides binding to class I molecules usually derive from proteins synthesized intracellularly (e.g., autologous proteins, tumor antigens, viruses, and other intracellular microbes), whereas class II molecules commonly bind peptides derived from proteins synthesized extracellularly (e.g., nonreplicating vaccines, extracellular bacteria). Endogenous peptides are loaded into newly synthesized class I molecules in the endoplasmic reticulum following active transport from the cytosol. Loading of exogenous peptides into class II molecules, in contrast, occurs in acidic endosomal vacuoles.

In addition to the recognition of lipids and lipid conjugates presented by CD1 molecules, there are other exceptions to the generalization that

MHC molecules only present (and T cells only recognize) oligopeptides. It has been known for many years that T cells can recognize haptens, presumably covalently or noncovalently complexed with peptides residing in the MHC-binding groove. This phenomenon is familiar to physicians as contact dermatitis to nonpeptide antigens such as urushiol (from poison ivy) and nickel ions.

Additionally, $\gamma\delta$ T cells can recognize a variety of nonpeptide antigens by a process that is not thought to require presentation by MHC molecules.²⁶ These antigens have been shown to include phosphorylated nucleotides, other phosphorylated small molecules, and alkylamines.

Another exception to the generalization of T-cell recognition of oligopeptides is represented by a group of proteins termed superantigens (SAg).²⁷ SAg, of which the staphylococcal enterotoxin A represents a prototype, are produced by a broad spectrum of microbes, ranging from retroviruses to bacteria. They differ from conventional peptide antigens in their mode of contact with both MHC class II molecules and TCR (Chapter 6). They do not undergo processing to oligopeptides, but rather bind to class II molecules and TCR as intact (~30 kDa) proteins outside the antigen-binding grooves. Their interaction with TCR is predominantly determined by polymorphic residues of the TCR V β region. Because SAg bind independently (more or less) of the TCR α -chain and the other variable segments of the β -chain, they are capable of activating much larger numbers of T cells than do conventional peptide antigens; hence the name. A secondary consequence of T-cell activation by SAg is death by apoptosis of appropriate V β -expressing cells. The initial response, however, is a wave of activation, proliferation, and cytokine production that can have profound clinical consequences, leading to development of such diseases as toxic shock syndrome. Interestingly, it is now apparent that certain bacterial products such as protein A of *Staphylococcus aureus* can similarly act on B cells, both to activate and then to delete, cells based on supraclonal binding to a site on products of the V_H3 gene family outside the conventional antigen-binding site. Such findings have led to the identification of a number of B-cell SAGs.²⁸

■ LYMPHOCYTE ADHESION AND TRAFFICKING ■

The capacity to survey continuously the antigenic environment is an essential element of immune function. APCs and lymphocytes must be able to find antigen wherever it occurs in the body. Surveillance is accomplished through an elaborate interdigitated circulatory system of blood and lymphatic vessels that establish connections between the solid organs of the peripheral immune system (e.g., spleen and lymph nodes) in which the cellular interactions between immune cells predominantly occur (Chapter 2).

The trafficking and distribution of circulating cells of the immune system are largely regulated by interactions between molecules on the surfaces of such cells with ligands on vascular endothelial cells (Chapter 3). The leukocyte-specific cellular adhesion molecules can be expressed constitutively or can be induced by cytokines (e.g., as a consequence of an inflammatory process). Two families of molecules, termed selectins and integrins, regulate lymphocyte traffic and insure that mobile cells home to appropriate locations within lymphoid organs and other tissues. Selectins are proteins characterized by a distal carbohydrate-binding (lectin) domain. They bind to a family of mucin-like molecules, the endothelial vascular addressins. Integrins are heterodimers essential for the emigration of leukocytes from blood vessels into tissues. Members of the selectin and integrin families are

not only involved in lymphocyte circulation and homing, but are also important in interactions between APC, T cells, and B cells in induction and expression of immune responses. A third family of adhesion molecules, distinguished as members of the IgSF, are similarly involved in promoting interactions between T cells and APCs (Chapter 12).

LYMPHOCYTE ACTIVATION

For both B cells and T cells, initial activation is a two-signal event^{29, 30} (Chapters 8 and 13). This generalization is particularly true for cells that have not been previously exposed to antigen. The first signal is provided by antigen. Most commonly, antigen for B cells is a protein with distinct sites (epitopes) that bind to membrane Ig. Such epitopes can be defined by a contiguous amino acid sequence or (more commonly) can be conformationally defined by the three-dimensional structure of the antigenic molecule. Epitopes can also be simple chemical moieties (haptens) that have been attached, usually covalently, to amino acid side chains (Chapter 6). In addition to proteins, some B cells have receptors with specificity for carbohydrates, and, less commonly, lipids or nucleic acids. Antigens that stimulate B cells can be either in solution or fixed to a solid matrix (e.g., a cell membrane). As previously noted, the nature of antigens that stimulate T cells is more limited. TCRs do not bind antigen in solution, but are generally only stimulated by small molecules, primarily oligopeptides, that reside within the antigen-binding cleft of a self-MHC molecule.

The second signal requisite for lymphocyte activation is provided by an accessory molecule expressed on the surface of the APC (e.g., B7/CD80) for stimulation of T cells or on the surface of a helper T cell (e.g., CD40L/CD154) for activation of B lymphocytes. The cell surface receptor for this particular second signal on T cells is CD28 and on B cells is CD40 (Fig. 1.3). Other cell surface ligand–receptor pairs may similarly provide the second signal²⁹ (Chapters 8 and 13). The growth and differentiation of both T cells and B cells also require stimulation with one or more cytokines, which are peptide hormones secreted in small quantities for function in the cellular microenvironment by activated leukocytes and APC.³¹

Cells stimulated only by antigen in the absence of a second signal become unresponsive to subsequent antigen stimulation (anergic) rather than being activated (Chapter 13). T cells can also be “tolerized” by minor changes in the sequence of the stimulatory antigenic peptide that can convert an activating (agonist) signal into an inactivating (antagonist) signal.³² This capacity to alter fundamentally the outcome of T-cell stimulation with minor changes in antigen suggests exciting opportunities for the development of future therapeutic agents.

Signal transduction through the antigen receptor is a complex process involving interactions between the specific receptor and a set of molecules co-expressed in the cell membrane. For B cells, this set of molecules is a heterodimer, Ig $\alpha\beta$, and for T cells it is a macromolecular complex, CD3, usually comprised of γ , δ , ϵ , and ζ chains.

Within the cell membrane, antigen receptor stimulation induces phosphorylation of CD3 subunits and hydrolysis of phosphatidylinositol 4,5-bisphosphate by phospholipase C, leading to generation of diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP₃). As a consequence of signal transduction and secondarily of DAG and IP₃ generation, tyrosine and serine/threonine protein kinases are activated. In turn, these kinases catalyze phosphorylation of a number of signal-transducing proteins, leading to activation of cytoplasmic transcription

Fig. 1.3 Reciprocal activation events involved in mutual simulation of T cells and B cells. T cells constitutively express T-cell receptors (TCR) and CD28. B cells constitutively express membrane immunoglobulin (mlg) and major histocompatibility complex (MHC) class II. Activation of B cells by antigen (Ag) upregulates expression of CD80 (B7) causing activation of T cells, which upregulates CD40L (CD154) and induces cytokine synthesis. Co-stimulation of B cells by antigen, CD40L, and cytokines leads to Ig production.

factors NF-AT and NF- κ B. These transcription factors then translocate to the nucleus, where they bind to 5' regulatory regions of genes that are critical to generalized lymphocyte activation^{33, 34} (Chapter 13).

CELL-MEDIATED IMMUNE RESPONSES

T-CELL SUBSETS

T lymphocytes expressing an $\alpha\beta$ TCR can be divided into two major subpopulations based upon the class of MHC molecule that their TCR recognizes and the consequent expression of one of a pair of TCR accessory molecules, CD4 or CD8 (Chapter 4). By binding to MHC molecules on APCs, CD4 and CD8 contribute to the overall strength of intercellular molecular binding. Additionally both molecules are involved in antigen receptor-mediated signal transduction. T cells expressing CD4, commonly referred to as T helper (Th) cells, recognize antigen bound to a nonpolymorphic region of class II MHC molecules. CD8 T cells recognize antigen bound to a nonpolymorphic loop on the α_3 domain of class I MHC molecules. The ratio of CD4 to CD8 cells in peripheral blood is usually about 2:1, but can normally vary over a considerable range (from approximately 0.8:1 to 3:1).

CD4 T CELLS, CYTOKINES, AND CHEMOKINES

The activities of CD4 T lymphocytes (CTLs) are predominantly mediated through the secretion of cytokines³¹ (Chapter 10). Cytokines are small (~12–30 kDa) protein hormones that control growth and

differentiation of cells in the microenvironment. This activity may include autostimulation (autocrine function) if the cell producing the cytokine also expresses a surface receptor for it, or stimulation of other cells in the microenvironment (paracrine function) including B cells, APC, and other T cells. Although it is now recognized that their biological effects are broader than implied by their name, many of the principal cytokines active in the immune system are known as interleukins (ILs).

The specific profile of cytokines produced by CD4 T cells allows further functional subdivision³⁵ (Chapters 16–18). Those CD4 T cells elaborating the “inflammatory” cytokines involved in effector functions of cell-mediated immunity, such as IL-2 and interferon (IFN)- γ , are designated Th1 cells. Other CD4 T cells synthesize cytokines such as IL-4 and IL-13 that control and regulate antibody responses, and are designated Th2 cells. Differentiation of Th1 versus Th2 subsets is a process regulated by positive-feedback loops, being promoted particularly by IL-12 in the case of Th1 cells and IL-4 in the case of Th2 cells. It is important to note that generalizations regarding cytokine activity are usually oversimplifications, reflecting a remarkable overlap and multiplicity of functions (Chapter 10). For example, although IL-2 was initially identified as a T-cell growth factor, it also significantly affects B-cell differentiation. The prototypic inflammatory cytokine, IFN- γ , which promotes differentiation of effector function of CTL and macrophages, is also involved in the regulation of Ig isotype switching. And IL-4, although known primarily as a B-cell growth and differentiation factor, can also stimulate proliferation of T cells.

A distinct subset of cytokines is a large group of highly conserved cytokine-like molecules, smaller than typical cytokines (~7–12 kDa), termed *chemotactic cytokines* or chemokines. Chemokines regulate and coordinate trafficking and activation of leukocytes, functioning importantly in host defenses, and also broadly in a variety of nonimmunological processes, including organ development and angiogenesis^{36, 37} (Chapter 11). They are characterized by binding to seven-transmembrane-domain G-protein-coupled receptors. The chemokines are classified based on number and spacing of cysteine residues. Of particular interest to clinical immunologists, two chemokine receptors are utilized by human immunodeficiency virus (HIV) as co-receptors (together with CD4) to gain entry into target cells.³⁸

Cytokines produced by activated T cells can downregulate as well as initiate or amplify immune responses.³⁹ Cytokines with such activity include IL-10 (produced by both T cells and B cells) and transforming growth factor- β (TGF- β). The functions of IL-10 *in vivo* are thought to include both suppression of the production of proinflammatory cytokines and enhancement of IgM and IgA synthesis. TGF- β is produced by virtually all cells and expresses a broad array of biological activities, including the promotion of wound healing and the suppression of both humoral and cell-mediated immune responses.

In addition to their central role in initiation and regulation of immune responses, CD4 T cells are important effectors of cell-mediated immunity (Chapter 17). Through the elaboration of inflammatory cytokines, particularly IFN- γ , they are essential contributors to the generation of chronic inflammatory responses, characterized histologically by mononuclear cell infiltrates, where their principal role is thought to be the activation of macrophages. Additionally, CD4 T cells, at least in some circumstances, are capable of functioning as cytotoxic effectors, either directly as CTL (in which case the killing is “restricted” for recognition of antigen-bound self-MHC class II) or through the elaboration of cytotoxic cytokines such as lymphotoxin and tumor necrosis factor- α (TNF- α).

A third subset of Th cells, designated Th17, has been recognized more recently.⁴⁰ With differentiation driven particularly by TGF- β and IL-23 and characterized by the production of the proinflammatory cytokine IL-17, Th17 cells are important in the induction and exacerbation of autoimmunity in a variety of disease models. Recent data also suggest a role of Th17 cells in host defenses against certain bacterial, fungal, and helminthic infections.

A further subset of CD4 cells, T regulatory cells (Tregs), suppresses the functions of other lymphocytes.⁴¹ Tregs can differentiate either in the thymus (natural Tregs) or in the periphery (induced or adaptive Tregs). They are characterized by surface expression of CD4 and CD25 and by nuclear expression of the transcription factor FOXP3. Activation of CD25⁺ Tregs is antigen-specific; the cells are IL-2-dependent and apparently require cell–cell contact for suppressive function. They can suppress functions of both CD4 and CD8 T cells, as well as B cells, NK cells, and NK T cells. In contrast to activation, suppressor effects are independent of the antigen specificity of the target cells. Other Tregs are noted for production of inhibitory cytokines, including TGF- β -secreting Th3 cells and IL-10-producing Tr1 cells.

CD8 T CELLS

The best understood function of CD8 T cells is that of cytotoxic effectors (CTL). Such cells are of particular importance in host defenses against virus-infected cells, where they are capable of direct killing of target cells expressing an appropriate viral peptide bound to a self-MHC class I molecule (Chapter 18). This process is highly specific and requires direct apposition of CTL and target cell membranes. Bystander cells, expressing inappropriate MHC molecules (e.g., that might be presented in an *in vitro* culture system) or different antigenic peptides are not affected. The killing is unidirectional; the CTL itself is not harmed and after transmission of a ‘lethal hit’ it can detach from one target to seek another. Killing occurs via two mechanisms: a death receptor-induced apoptotic mechanism, resulting in fragmentation of target cell nuclear DNA, and a mechanism requiring insertion of perforins and granzyme from the CTL into the target cell. CTL activity is enhanced by IFN- γ . As CTL function is dependent upon cell surface display of MHC class I molecules, a principal mechanism of immune evasion by viruses and tumors is elaboration of factors that downregulate class I expression (Chapter 27). As noted above, however, this increases susceptibility of such cells to cytolytic activity of NK cells.

■ ANTIBODY-MEDIATED IMMUNE RESPONSES ■

The structure of antibodies permits the possibility of a virtually limitless binding specificity of its antigen-binding groove, determined by the sequence variability of the amino-terminal segments of its light and heavy chains (Fab portion). Antigen binding can then be translated into biological effector functions based on the properties of the larger nonvariable (constant) portions of its heavy chains (Fc fragment) (Chapter 15). Moreover, in response to cytokines in the cellular microenvironment, through the mechanism of isotype switching, an antibody-producing cell can alter the biological effects of its secreted product without affecting its specificity. With functional heterogeneity determined by isotype, the antibody molecules provide an efficient

KEY CONCEPTS

BIOLOGICAL PROPERTIES OF IMMUNOGLOBULIN (IG) CLASSES

- >> IgM: Principal Ig of primary immune responses
 - Generally restricted to vascular compartment
 - B-cell antigen receptor (monomer)
 - Fixes complement
- >> IgG: Principal Ig of secondary immune responses
 - Binds to Fc γ receptors on neutrophils, monocytes/macrophages, NK cells
 - Fixes complement (except IgG₄ subclass)
- >> IgA: Principal Ig of mucosal immunity
- >> IgD: B-cell antigen receptor
- >> IgE: Binds to Fc ϵ receptors on mast cells and basophils
 - Antibody of immediate hypersensitivity
 - Important in defenses against helminths

defense system against extracellular microbes or foreign macromolecules (e.g., toxins and venoms) (Chapters 15 and 24).

Each of the antibody classes contributes differently to an integrated defense system. IgM is the predominant class formed upon initial contact with antigen (primary immune response). As a monomeric structure comprised of two light (κ or γ) and two heavy (μ) chains, it is initially expressed as an antigen receptor on the surface of B lymphocytes. It is secreted, however, as a pentamer composed of five of the monomeric subunits held together by a joining (J) chain. IgM is essentially confined to the intravascular compartment. As a multivalent antigen binder that can efficiently activate complement, it is an important contributor to an early immune response. Moreover, the synthesis of IgM is much less dependent than other isotypes upon the activity of T lymphocytes.

IgG is the most abundant immunoglobulin in serum and the principal antibody class of a secondary (anamnestic or memory) immune response. The structure of an IgG molecule is similar to an IgM monomer, i.e., two light (κ or γ) and two heavy (μ) chains joined by interchain disulfide bridges. Because of its abundance, its capacity to activate (fix) complement, and the expression on phagocytes of Fc γ receptors, IgG is the most important antibody of secondary immune responses. IgG has an additional important property of being the only isotype that is actively transported across the placenta. Thus, infants are born with a full repertoire of maternal IgG antibodies, at concentrations often greater than those found in the mother's serum. Maternal antibodies provide the neonate with an important level of antibody protection during the early months, when its own antigen-driven antibody responses are primordial.

IgA is the principal antibody in the body's secretions (Chapter 19). It is found in serum in monomeric form of two light and two heavy (α) chains or as a dimer joined by J chain. In secretions, it is usually present as a dimer also joined by J chain and is actively secreted across mucous membranes by attachment of a specialized secretory component. It is found in high concentration in tears, saliva, and the secretions of the respiratory, gastrointestinal, and genitourinary systems and is relatively resistant to enzymatic digestion. It is particularly abundant in colostrum,

where its concentration may be greater than 50 times that in serum, providing passive immunity through this class of antibody to the gastrointestinal system of a nursing neonate. IgA does not fix complement by the antibody-dependent pathway. Hence, its role in host defenses is not through the promotion of phagocytosis, but rather in preventing a breach of the mucous membrane surface by microbes or their toxic products.

IgD and IgE are present in serum at concentrations much lower than that of IgG. The biological role of secreted IgD, if any, is unknown. However, IgD is important as a membrane receptor for antigen on mature B cells. Moreover, the molecular mechanisms promoting isotype switching from IgM to IgM/IgD are substantially different from those for other isotypes and can occur independent of a T-cell-regulated process.

Although IgE is the least abundant isotype in serum, it has dramatic biological effects because it is responsible for immediate-type hypersensitivity reactions, including systemic anaphylaxis (Chapter 42). Such reactions are a consequence of the expression of high-affinity receptors for Fc ϵ on the surfaces of mast cells and basophils. Cross-linking of IgE molecules on such cells by antigen induces their degranulation, with the synthesis and/or release of the potent biological mediators of immediate hypersensitivity responses. The protective role of IgE is in host defenses against parasitic infestation, particularly helminths (Chapter 29).

COMPLEMENT AND IMMUNE COMPLEXES

As noted, the biological functions of IgG and IgM are largely reflections of their capacities to activate the complement system. Through a series of sequential substrate–enzyme interactions, the 11 principal components of the antibody-dependent complement cascade (C1q, C1r, C1s, and C2–9) effect many of the principal consequences of an antigen–antibody interaction (Chapter 20). These consequences include the establishment of pores in a target membrane by the terminal components (C5–9) leading to osmotic lysis; opsonization by C3b, promoting phagocytosis; the production of factors with chemotactic activity (C5a); and the ability to induce degranulation of mast cells (C3a, C4a, and C5a). There are three distinct pathways to complement activation.^{42, 43} The pathway mediated by the binding of IgG or IgM to the first component (specifically C1q), has been termed the 'classical' pathway. The lectin pathway is similar to the classical pathway but is activated by certain carbohydrate-binding proteins, the mannose (or mannan)-binding lectin (MBL) and ficolins, which recognize certain carbohydrate repeating structures on microorganisms. MBL and ficolins are plasma proteins that are homologous to C1q and contribute to innate immunity through their capacity to induce antibody- and C1q-independent activation of the classical pathway. Finally, a large number of substances, including certain bacterial, fungal, and viral products, can directly activate the cascade through a distinct series of proteins, also leading to activation of the central C3 component. Although bypassing C1, C4, and C2, this distinct pathway results in all the biological consequences of C3–9 activation. Nonantibody-induced activation of C3 is referred to as the alternative or properdin pathway. Reflecting these separate pathways to activation, the complement system is a major contributor to the efferent limbs of both innate and acquired immune systems.

In addition to their roles in pathogen/antigen elimination, constituents of the complement system, together with antigen–antibody (immune) complexes, act at leukocyte surfaces to regulate immune functions.⁴⁴ For

example, interaction of immune complexes via FcγR on B cells decreases their responsiveness to stimulation. In contrast, complement activation on B-cell surfaces co-ligates their receptors with B-cell receptors for antigen; the cells are more readily activated and become relatively resistant to apoptosis.

■ APOPTOSIS AND IMMUNE HOMEOSTASIS ■

An immune response is commonly first viewed in a ‘positive’ sense, i.e., lymphocytes are activated, proliferate, and carry out effector functions. It is equally important, however, that this positive response be tightly regulated by mechanisms that operate to turn off the response and eliminate cells no longer required. Under physiologic circumstances, once an immune response fades, commonly as a consequence of antigen depletion, two pathways to terminal lymphocyte differentiation become available: apoptosis or differentiation into memory cells. Memory cells are, of course, a key to the effectiveness of the adaptive immune system. Once seen effectively, a second encounter with antigen (e.g., pathogen) is both more rapid and more effective. IgG antibodies are rapidly produced and/or clones of CTL effector cells are rapidly expanded as a consequence of prior exposure and clonal expansion. But the majority of lymphocytes in an active response are not required for maintenance of immunologic memory, and for these larger populations a need for immune homeostasis leads to apoptosis.⁴⁵

Apoptosis is a unique process of cellular death, widely conserved phylogenetically, and distinguished from death by necrosis by cellular shrinking, DNA fragmentation, and breakdown of cells into “apoptotic bodies” containing nuclear fragments and intact organelles (Chapter 14). The process depends upon the activation of cysteinyl proteases, termed caspases, that cleave proteins involved in DNA repair and cellular and organelle architecture at specific aspartyl residues. In the absence of such mechanisms, massive proliferation of lymphoid tissues is a consequence, seen clinically as the autoimmune lymphoproliferative syndrome or ALPS, which is characterized by lymphocytosis with lymphadenopathy and splenomegaly, as well as autoimmunity and hypergammaglobulinemia (Chapter 35).

■ HOST IMMUNE DEFENSES REVISITED ■

The first response upon initial contact with an invading pathogen depends upon components of the innate immune system. This response begins with expression of pathogen-associated molecular patterns (PAMPs), such as lipoproteins, lipopolysaccharide, CpG-DNA, and bacterial flagellin, among others. PAMPs bind to pattern recognition receptors (PRRs) on effector cells of the innate immune system, including dendritic cells, granulocytes, and lymphocytes. The best-characterized PRRs are the 11 Toll-like receptors (TLRs), first recognized as determinants of embryonic patterning in *Drosophila* and subsequently appreciated as components of host defenses in both insects and mammals.^{46, 47} TLR subfamilies can be distinguished by expression either on the cell surface or in intracellular compartments. Binding of TLRs by a PAMP ligand triggers intracellular signaling pathways via multiple “adaptors” leading to a vigorous inflammatory response. Based on involvement of the myeloid differentiation primary response gene 88 (MyD88), two principal pathways are recognized. Most TLRs are MyD88-dependent, whereas TLR3 and -4 signal via a MyD88-independent IFN-β pathway.

As noted above, the innate immune response also includes the capacity of NK lymphocytes to identify and destroy, by direct cytotoxic mechanisms, cells lacking surface expression of MHC class I molecules, which marks them as potentially pathogenic.⁷ Additionally, an innate immune response involves elements of the humoral immune system that function independently of antibody, especially the activation of the complement cascade through the lectin and alternative pathways, with consequent opsonization to promote phagocytosis and destruction.

The defenses of the specific immune system to any particular pathogenic agent are determined largely by the context in which it is encountered. Regardless, effectiveness depends upon the four principal properties of specific immunity: (1) a virtually unlimited capacity to bind macromolecules, particularly proteins, with exquisite specificity, reflecting random generation of antigen-binding receptors; (2) the capacity for self/nonself discrimination, consequences of a rigorous process involving positive and negative selection during thymocyte differentiation as well as negative selection during B-cell differentiation; (3) the property of immunological memory, reflecting antigen-driven clonal proliferation of T cells and B cells that results in increasingly rapid and effective responses upon second and subsequent encounters with a particular antigen or pathogen; and (4) mechanisms for pathogen destruction, including direct cellular cytotoxicity, release of inflammatory cytokines, opsonization with antibody and complement, and neutralization in solution by antigen precipitation or conformational alteration.

Although most specific immune responses involve a multiplicity of available defense mechanisms, several generalizations may be conceptually useful. NK-cell- and T-cell-mediated effector functions are particularly important in defenses against pathogens encountered intracellularly, such as viruses and intracellular bacteria. These responses involve the production of inflammatory cytokines by CD4 Th1 cells, as well as the direct cytolytic activity of CD8 CTL. In contrast, host defenses to most antigens encountered primarily in the extracellular milieu are largely dependent upon humoral mechanisms (antibody and complement) for antigen neutralization, precipitation, or opsonization and subsequent destruction by phagocytes. Targets of antibody-mediated immunity include extracellular bacteria and toxins (or other foreign proteins). It is worth reiterating, however, that induction of an effective antibody response (including isotype switching) and development of immunological memory (resulting from B-cell clonal expansion) require antigen activation not only of specific B cells, but also CD4 T cells, particularly of the Th2 type.

Finally, clinical ‘experiments of nature’ have proven particularly instructive in our efforts to understand the role of specific components of the immune system in overall host defenses⁴⁸ (Chapter 31). The importance of T-cell-mediated immunity in host defenses to intracellular parasites, fungi (Fig. 1.4), and viruses is emphasized by the remarkable susceptibility of T-cell-deficient patients to organisms such as *Pneumocystis jiroveci* and *Candida albicans*, as well as by the risks of utilizing attenuated live virus vaccines in such patients. On the other hand, patients with defects in antibody synthesis or phagocytic cell function are characteristically afflicted with recurrent infections with pyogenic bacteria, particularly Gram-positive organisms; patients with inherited defects in synthesis of terminal complement components have increased susceptibility to infection with species of *Neisseria*.

In recent years immunology has entered the lay lexicon, largely as a result of the HIV pandemic. People throughout the world are now tragically aware of the consequences of immune deficiency. The

CLINICAL RELEVANCE

CHARACTERISTIC INFECTIONS ASSOCIATED WITH IMMUNE DEFICIENCY SYNDROMES

- >> Deficiencies of T-cell-mediated immunity
 - Mucocutaneous fungal infections, especially *Candida albicans*
 - Systemic (deep) fungal infections
 - Systemic infection with attenuated viruses (e.g., live viral vaccines)
 - Infection with viruses of usually low pathogenicity (e.g., cytomegalovirus)
 - Pneumocystis jiroveci* pneumonia
- >> Antibody deficiencies
 - Encapsulated bacterial infections (e.g., *Streptococcus* spp., *Haemophilus influenzae*)
 - Recurrent pneumonia, bronchitis, sinusitis, otitis media
 - Giardia lamblia* enteritis
- >> Phagocyte deficiencies
 - Gram-positive bacterial infection (e.g., staphylococci, streptococci)
 - Gram-negative sepsis
 - Systemic fungal infections (e.g., *Candida* spp., *Aspergillus* spp.)
- >> Adhesion molecule deficiencies
 - Pyogenic bacterial infections (especially staphylococci)
 - Cutaneous and subcutaneous abscesses
- >> Complement component deficiencies
 - C3 deficiency – infections with encapsulated bacteria
 - Deficiency of terminal components – Gram-negative bacteria, especially *Neisseria* spp.

remarkable progress in understanding of this disease, however, depended substantially upon earlier studies of relatively rare patients with primary immunodeficiency syndromes. Similarly, cure of patients with primary immunodeficiencies by cellular reconstitution, particularly bone marrow transplantation, presaged recent interest in correction of such diseases by gene replacement, which, despite formidable challenges, is likely to lead to cures of numerous other, more common, diseases in the foreseeable future. The 'present' of clinical immunology is indeed bright, but its future potential to impact prevention and treatment of many diseases that are today immense challenges is even more exciting to contemplate.⁴⁹

Studies in experimental animal systems, especially the mouse, have been critical to our understanding of molecular aspects of immune system function and have contributed importantly to our appreciation of how aberrations of such functions are involved in the pathogenesis of disease. The new insights gained from use of transgenic mice (including murine expression of human genes) and constitutive or conditional gene knockout mice suggest that future progress will equally depend upon detailed analysis in such systems. Nevertheless, the carefully studied patient will remain the ultimate crucible for understanding human immunity and the roles of the immune system in the pathogenesis of and protection from disease.

Fig. 1.4 Leg of a 16-year-old patient with chronic mucocutaneous candidiasis as a consequence of congenital T-cell deficiency associated with hypoparathyroidism.

Organization of the immune system

Dorothy E. Lewis, Gregory R. Harriman,
Sarah E. Blutt

2

The human immune system consists of organs, including the spleen, the thymus, and the lymph nodes; and movable cells, including cells from bone marrow, blood and lymphatics. This design allows central locations for the initial production and differentiation of committed cells from naive precursors, as in the fetal liver, the bone marrow and the thymus; and more dispersed sites for the selection and further differentiation of cells into mature effector cells, as in the spleen, lymph nodes and intestinal Peyer's patches. This arrangement also allows the regulation of immune responses at locations peripheral to the primary lymphoid organs, and thus provides local control of infectious processes. The mechanisms responsible for the ability of nonspecific leukocytes and natural killer (NK) cells and antigen-specific T and B lymphocytes to respond rapidly to an assault are discussed in later chapters. This chapter is concerned with the basic features and the ontogeny of the cells involved with both specific and nonspecific immunity, and with the essential structure of the lymphoid organs.

IMMUNE CELL DEVELOPMENT

ONTOGENY OF THE CELLS OF THE IMMUNE SYSTEM

In the first month of embryogenesis in humans, stem cells capable of producing white blood cell progenitors can be found in yolk sac erythropoietic islands that are physically attached to, but not inside, the embryo.¹ A specialized endothelial cell is thought to give rise to the first progenitor cell.² An area adjacent to the liver, called the aorta-gonad-mesonephros (AGM), produces the progenitor cells that will subsequently develop into hematopoietic stem cells, as classically defined. The placenta has been identified as a separate possible source for fetal stem cells for both the AGM and the fetal liver.³ The embryonic liver is the first organ to be populated by these progenitor stem cells. It begins the process of blood cell production in the sixth week of gestation, or just after the organ can first be identified histologically. By the 11th week, the liver is the major source of hematopoiesis and will remain the major organ until the sixth month of gestation.

The first progenitor cells derived from hematopoietic stem cells (HSC) are colony-forming cells that can differentiate into granulocytes, erythrocytes, monocytes, megakaryocytes, and lymphocytes. The elements of the skeleton are formed between the second and fourth months of gestation. After this process is complete, white blood cell development shifts to the marrow of these bones. The transition from liver to bone marrow is completed in the sixth month of gestation. Cells that differentiate from early stem cells begin to populate the primary lymphoid organs, such as the thymus, by 7–8 weeks' gestation.⁴ At 8 weeks' gestation, T-cell precursors that have initiated T-cell receptor (TCR) rearrangement (Chapter 9) can be detected in thymic tissue. In the fetal liver, B-cell precursors initiate immunoglobulin (Ig) rearrangements by 7–8 weeks' gestation (Chapter 8). Late in the first trimester, B-cell development spreads to the bone marrow. In the bone marrow, B-cell progenitors congregate in the areas adjacent to the endosteum and differentiate in the direction of the central sinus. The association of B cells with stromal reticular cells is thought to be essential for the eventual release of mature B cells into the central sinus. As in the case of T-cell development, a selection process causes many B-cell progenitors to die by apoptosis.

In adult humans the bone marrow is the chief source of stem cells. However, the peripheral blood contains a population of stem cells with somewhat different characteristics that are capable of limited self-renewal.⁵

TOOLS ESSENTIAL TO AN UNDERSTANDING OF IMMUNE CELL BIOLOGY

Progress beyond morphologic categorization of hematopoietic cells has been facilitated in the last 20 years by the creation of a series of monoclonal antibodies that can be used to identify stage-specific leukocyte cell surface antigens using flow cytometry. These antibodies can also be used for functional characterization. In the early 1980s, the sheer number of monoclonal antibodies raised against a multitude of human leukocyte antigens yielded a complicated nomenclature. In response, leukocyte differentiation antigen workshops were convened to provide guidance, a consistent nomenclature, and consensus regarding the reactivities of

KEY CONCEPTS

CELLS OF THE IMMUNE SYSTEM

- >> Pluripotent stem cells in the bone marrow give rise to all the lineages of immune cells.
- >> The development and regulation of cells of the immune system is associated with the programmed appearance of specific cell surface molecules and responsiveness to selective cytokines.
- >> The mature cells of the immune system include the antigen-presenting cells of various types; other phagocytic cells, including neutrophils, eosinophils and basophils; and lymphocytes, which are T, B or natural killer cells.
- >> Each lymphocyte lineage can be divided into discrete subpopulations which subserve specialized functions. These include CD4 and CD8 T cells, T-helper (Th) subsets, CD16⁺ and CD16⁻ NK cells, and CD5⁺ (B1) and CD5⁻ (B2) B cells.

monoclonal antibody preparations. All the monoclonal antibodies that recognized a single molecule on leukocytes were grouped by the cluster pattern of cells with which they were identified, hence the term CD, or 'cluster of differentiation' antigen (Table 2.1). As of 2005, 339 CD antigens had been officially recognized, with varying levels of characterization (see Appendix 1). The identification of distinctive patterns of CD antigen expression is an important tool in understanding cellular subpopulations, the relationships between differentiating progenitor subpopulations, and the effector functions of the various cells of the immune system. Future workshops will focus on markers of functional subsets of cells. A more extensive discussion of these markers can be found at <http://www.hcdm.org>.

HEMATOPOIESIS AND LYMPHOPOIESIS

All mature cells of the hematopoietic and lymphoid lineages are derived from the same population of pluripotent stem cells.⁶ These cells first give rise to hematopoietic and lymphoid progenitors. The hematopoietic

Table 2.1 Important cell surface antigens on hematopoietic cells

Cell type	Surface antigens	Predominant location
Hematopoietic stem cells		
Bone marrow HSC	CD34 ⁺ or CD34 ⁺ , Lin ⁻ , Thy1 ⁺	Bone marrow
Peripheral blood HSC	CD34 ⁺ , Lin ⁻ , CD38 ⁺ , CD71 ⁺	Blood
Myeloid cells		
Monocytes	CD14 CD35 (CR1), CD64 (FcRγ1)	Blood
Macrophages	CD68, CD13, CD64, CD35	Tissues
Langerhans' cells	CD1a, CD207 (Langerin),	Skin
Follicular dendritic cells	CD35, CD64	B-cell areas, lymph nodes
Interdigitating Dendritic cells	CD80, CD56, Class II, CD83, CD40	T cell areas, lymph nodes Mainly tissues
Dendritic cells	CD83, CD80, CD86, CD40	
Plasmacytoid dendritic cells (IFN-α producing)	CD4, CCR5, CXCR4, CD40	
Granulocytes		
Neutrophils	CD16 (FcγRIII), CD35 CD88 (C5aR)	Blood, tissues
Eosinophils	CD32 (FcγRII)	Blood, tissues
Basophils	CD23, (FcεRII), CD32	Tissues, blood
Mast cells	FcεRI Alpha FcεRI Alpha	Tissues, blood, Tissues
Lymphocytes		
T cells	CD7, CD3, CD4, CD8, CD28	Thymus, spleen, lymph nodes, MALT, blood
B cells	Surface Ig, class II, CD19, CD20, CD22, CD40	Bone marrow, spleen, lymph nodes, MALT, blood
NK cells	CD16, CD56, CD94	Spleen, lymph nodes, mucosal tissues, blood
NKT cells	CD3, CD56, Vα24 TCR	Blood, tissues
Tregs	CD4, CD25, Foxp3	Thymus, blood, tissues

progenitors are subsequently capable of maturing into cells of the granulocytic, erythroid, monocytic–dendritic, and megakaryocytic lineages (GEMM colony-forming units, CFU-GEMM). Likewise, lymphoid progenitors mature into B lymphocytes, T lymphocytes and NK cells (Fig. 2.1).

In the adult, hematopoiesis and lymphopoiesis occur in two distinct tissues. The development of hematopoietic lineage cells – that is, granulocytes, monocytes, dendritic cells, erythrocytes and platelets – occurs in the bone marrow (Table 2.2). B-lymphocyte development, through the stage of mature B cells, also occurs in the bone marrow (Chapter 8). On the other hand, T-cell progenitors leave the bone marrow, migrate to the thymus and differentiate into $\alpha\beta$ and $\gamma\delta$ T cells, as well as regulatory T cells (Chapter 9). Evidence also suggests that at least some NK cells develop from precursors in the thymus.⁷ However, most NK cell development occurs extrathymically, mainly in the bone marrow.

CHARACTERISTICS OF HEMATOPOIETIC STEM CELLS

The pluripotent stem cell is thought to give rise to all the major red and white blood cell populations. Human hematopoietic stem cells (HSC) in the bone marrow are rare: 1 in 10 000 cells. They occupy a distant niche in the bone marrow closest to the bone and rely on osteoblasts for this localization.⁸ Several separation methods have been used to study stem cells and their differentiative potential in detail. Early observations showed that the HSC had characteristic flow cytometric light-scattering properties (low side scatter, medium forward scatter), no lineage (LIN)-specific markers (e.g., CD2, CD3, CD5, CD7, CD14, CD15 or CD16), and expressed CD34 on the cell surface.⁹ However, hematopoietic reconstitution can occur with CD34⁺, noncycling LIN[−] cells, suggesting that surface expression of CD34 is not a definitive marker of the most primitive precursors.¹⁰

A subpopulation of stem cells excludes nucleophilic dyes such as Hoechst dye and is called a ‘side population’, which can give rise to a wide variety of cell types. A key aspect of a long-term stem cell is its capacity for self-renewal via asynchronous division.¹¹

Hematopoietic stem cells circulate in the peripheral blood with 10–100 times less frequency. Mobilization of ‘stem cells’ to the periphery can be induced with G-CSF. Of these, about 5–20% are true stem cells.¹² Enriched peripheral blood stem cells do not express lineage-associated antigens. A minor subpopulation expresses the B-cell antigens, CD19 and CD20, and there is a variable level of expression of the myeloid CD33 and CD13 antigens. Most peripheral blood stem cells express activation antigens, such as the transferin receptor, CD71 and CD38. Peripheral blood HSC cells can engraft 2–3 days faster than conventional bone marrow HSC. Peripheral blood HSC are slightly more differentiated than those obtained from the bone marrow.

REGULATION OF HEMATOPOIETIC AND LYMPHOPOIETIC CELL GROWTH AND DIFFERENTIATION

Regulation of stem cell differentiation occurs through interactions with a variety of microenvironmental factors in the bone marrow or thymus. Cell surface receptors recognize either soluble ligand (e.g., cytokines)

released by other cells, or surface ligands (e.g., cell interaction molecules) expressed on adjacent cells. These receptors can facilitate differentiation. Stem cells can be exposed to spatially and temporally regulated ligands or factors. The differential expression of receptors on the stem cells allow control of proliferation and differentiation along one of the hematopoietic or lymphoid lineages.¹³

Cytokines have pleiotropic effects on hematopoietic and lymphoid cell development. They affect both the growth and maintenance of pluripotent stem cells, as well as the development and differentiation of specific cell lineages. The effect of the cytokine often differs, depending on whether the cell has previously been or is concurrently being stimulated by other cytokines. The stage of differentiation, as well as the presence or absence of the cytokine’s receptor on the cell surface, also affects the cellular response.

Stromal cells located within the bone marrow and thymus regulate hematopoietic and lymphoid cell growth and differentiation by releasing cytokines, such as the interleukins IL-4, IL-6, IL-7 and IL-11; leukemia inhibitory factor (LIF); granulocyte–macrophage colony-stimulating factor (GM-CSF); granulocyte colony-stimulating factor (G-CSF); and stem cell factor (SCF).¹⁴ Stromal cells also participate in cell–cell interactions with progenitors by means of the engagement of cell surface molecules that provide additional regulatory stimuli. In addition, stromal cells form the intercellular matrix (e.g., fibronectin and collagen) that binds to selectin and integrin receptors present on hematopoietic and lymphoid progenitors.¹⁵

Cytokines that affect the growth and maintenance of pluripotent and multipotent stem cells

Pluripotent stem cells are characterized by their ability to reconstitute cells of the hematopoietic and lymphoid lineages.¹⁶ Stem cells are resistant to 5-fluorouracil treatment, which indicates that they are nondividing. The factors that maintain these cells, as well as those that promote their growth, are becoming better understood. Maintenance of pluripotent capacity is mediated through differentiation antagonists, termed restrictins. Studies suggest that stromal cells maintain stem cell capacity by the release of factors such as restrictin-D or flt-3/flk-2 ligand, which either antagonize differentiation induced by other cytokines or facilitate stem cell self-renewal. Because the stem cell pool is depleted as their progeny differentiate, proliferation of the stem cells is required to avoid exhaustion. The entry of stem cells into the cell cycle and subsequent proliferation, as well as commitment to particular lineages, also appears to be controlled by cytokines. Recent studies have focused on discovery of *in vitro* conditions that maintain extended long-term cultures of stem cell populations. The data suggest that flt-3 ligand, *c-kit* ligand and megakaryocyte growth and development factor (MGDF) all promote long-term stem cell expansion. The combination of *c-kit* ligand, IL-3 and IL-6 causes more rapid expansion, but does not allow long-term extension of precursor cells.¹⁶

Several cytokines, either alone or in combination, have been shown to promote stem cell growth (Table 2.3).¹⁷ In general, combinations of cytokines are more effective at inducing stem cell growth than are individual cytokines. For example, IL-1 promotes stem cell growth by its ability to induce bone marrow stromal cells to release additional cytokines. In addition, although IL-1 cannot stimulate hematopoietic progenitors by itself, it can synergistically stimulate these cells in the presence of other cytokines. One of these other cytokines, IL-3, promotes the growth of hematopoietic progenitors.

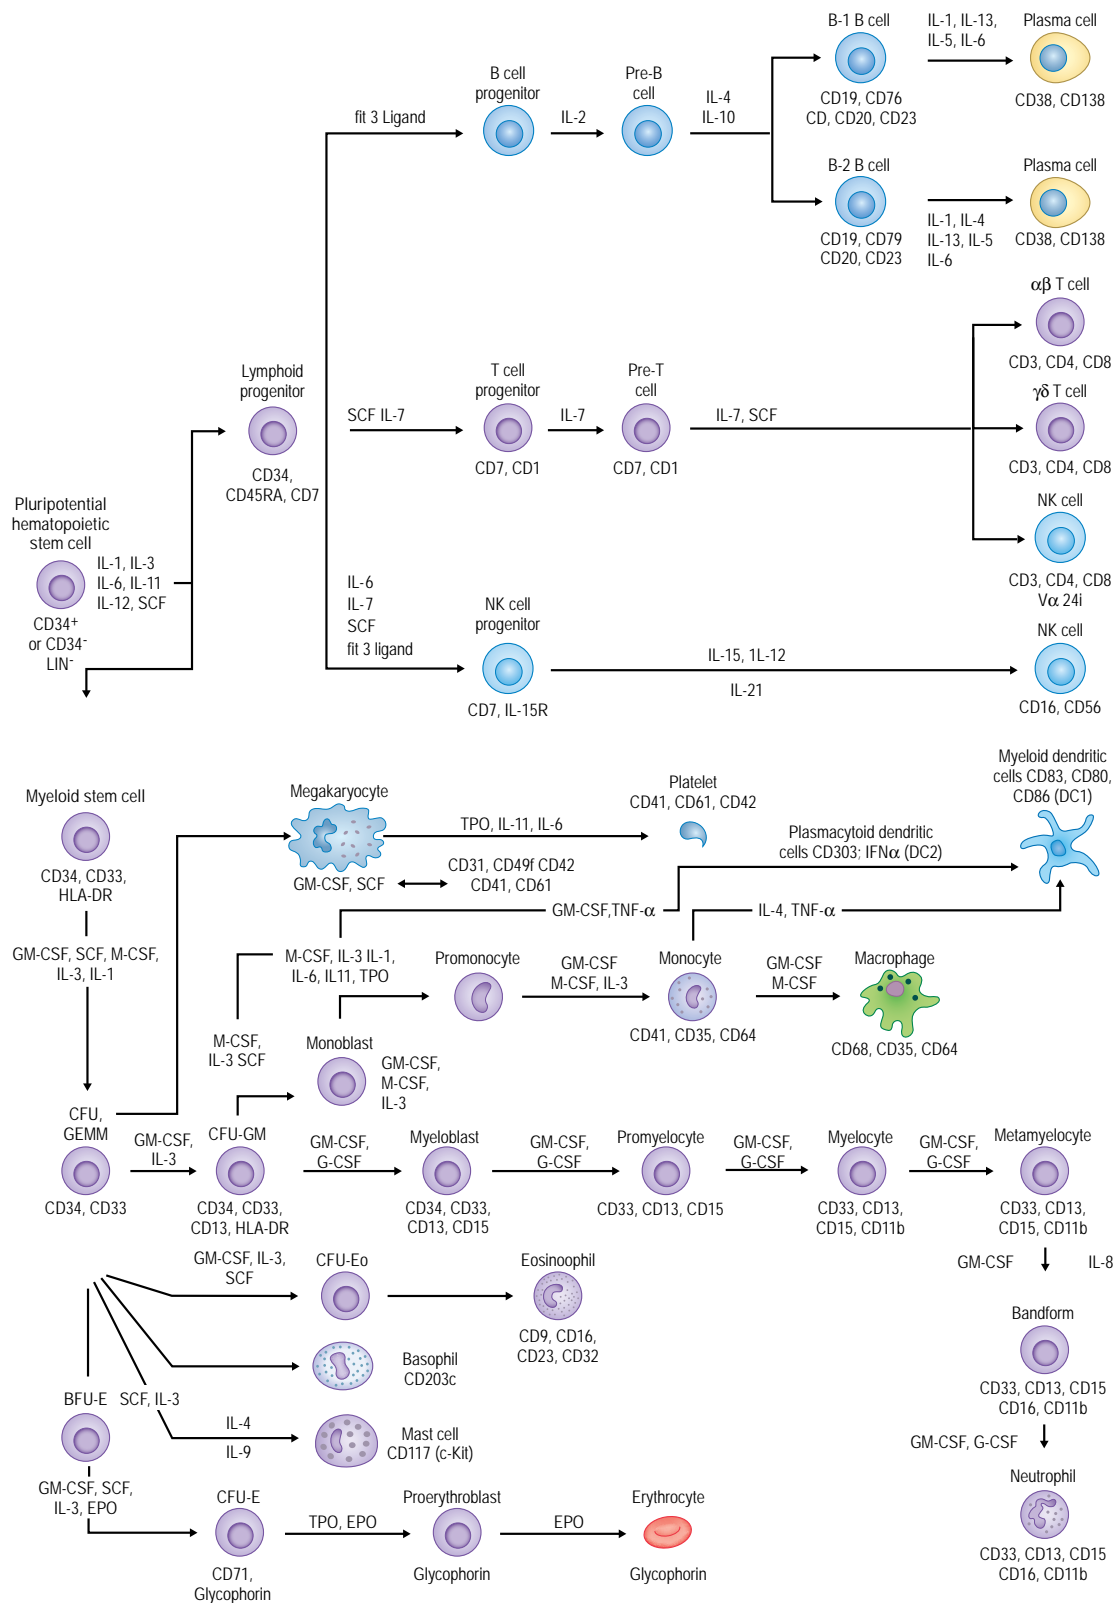

Fig. 2.1 The differentiation of hematopoietic cells.

Table 2.2 Normal distribution of hematopoietic cells in the bone marrow

Cell type	Approximate proportion (%)
Stem cells	1
Megakaryocytes	1
Monocytes	2
Dendritic cells	2
Lymphocytes	15
Plasma cells	1
Myeloid precursors	4
Granulocytes	50–70
Red blood cell precursors	2
Immature and mature red blood cells	10–20

The effect is significantly enhanced by IL-6, IL-11, G-CSF and SCF. IL-11, a stromal cell-derived cytokine, enhances IL-3-induced colony formation in 5-fluorouracil-resistant stem cells. Similarly, other cytokines secreted by stromal cells, for example IL-6, G-CSF and SCF, also exert their effects by shortening the G_0 period in stem cells. In contrast, IL-3 acts on cells after they have left G_0 . IL-12 is unable to support the growth of primitive hematopoietic stem cells, either by itself or in conjunction with IL-11 or SCF. However, it does act in synergy with IL-3 and IL-11, or IL-3 and SCF, to enhance stem cell survival and growth. In some situations, cytokines can enhance the growth of hematopoietic and lymphoid cells, but under other circumstances the cytokine may inhibit cell growth or enhance differentiation. LIF is a cytokine that demonstrates such pleiotropic effects. One feature of LIF is that it enhances the growth and development of bone marrow progenitor cells along multiple lineages in media containing IL-3, IL-6 and GM-CSF. However, in the absence of cytokines or factors in serum, LIF has little effect on the growth and development of CD34⁺ progenitor cells. Similarly, although transforming growth factor- β (TGF- β) and IL-4 are

Table 2.3 Cytokines important for hematopoietic cell growth and differentiation

Cytokines	Stem cells	Thymocytes	B cells	NK cells
IL-1	Acts on Stromal cells	Differentiation		
IL-2		Pleomorphic	Proliferation	Proliferation
IL-3	Proliferation			
IL-4		Pleomorphic	Promotes (low) Prevents (high)	Inhibits IL-2
IL-5			Proliferation/differentiation	
IL-6	Shortens G_0	Enhances stimulation	Maintains potential	Enhances IL-2
IL-7		Survival/proliferation	Proliferation of pro- and pre-B cells	Activation
IL-10			Survival	
IL-11 Oncostatin M	Shortens G_0		Maintains potential	
IL-12	Survival			Activation Proliferation
IL-13			Activation/division of mature B cells	
IL-15			Proliferation	Development/survival
Interleukin 21			Proliferation	Expansion
SCF/c-kit	Survival	Atrophy	Maintains potential	Expansion
G-CSF	Shortens G_0		Maintains potential	
FLT3 ligand	Growth Factor		Increases proliferation	Expansion
SDF1- α		Proliferation/Regeneration	Chemoattractant	
LIF	Proliferation	Atrophy		
Thrombopoietin	Expansion			
TNF- α	Proliferation: inhibits granulocytes			
TGF- β	Inhibits growth enhanced granulocytes			
MIP-1 α	Inhibits			
NGF			Proliferation/differentiation	Expansion

potent inhibitors of hematopoietic progenitor cell growth, they have been shown to enhance granulocyte development. Conversely, although tumor necrosis factor- α (TNF- α) inhibits the development of granulocytes, it can potentiate the effects of IL-3 on hematopoietic progenitor cell proliferation.

Other cytokines have effects on the proliferation and differentiation of multipotent progenitors of hematopoietic and lymphoid cells. For example, GM-CSF and IL-3 promote the development of granulocytes, macrophages, dendritic cells and erythrocytes. Similarly, IL-6 participates in the development of neutrophils, macrophages, platelets, T cells and B cells.

Cytokines that inhibit hematopoietic stem cell growth

Cytokines produced by mature cells also downregulate hematopoietic stem cell growth. For example, macrophage inflammatory protein-1 α (MIP-1 α) is an inhibitor of hematopoietic progenitor cell proliferation. Other factors regulate stem cell growth through a variety of mechanisms, including the promotion of terminal differentiation (e.g., interferon- γ [IFN- γ] and TGF- β) or through the induction of apoptosis (e.g., TNF- α). When pathologic conditions exist, these cytokines can have adverse effects on hematopoietic and lymphoid cell development, resulting in various deficiency states.

Cytokines affecting development and differentiation of specific cell lineages

The initial event in differentiation involves the commitment of pluripotent stem cells to a specific lineage. Cytokines are important for this process and appear to have lineage-specific effects that act specifically at late stages of differentiation. For example, erythropoietin regulates the later stages of erythrocyte differentiation, whereas G-CSF induces granulocyte differentiation and macrophage colony-stimulating factor (M-CSF) is specific for macrophage maturation.¹⁸ Cytokines that play

an important role in the growth and development of specific cell lineages are described under each cell type.

Mature cells of the immune system

The mature cells of the immune system, which arise mainly from progenitor cells in the bone marrow, include nonspecific effector cells and antigen-specific effector cells. The central player in both lines of defense is the antigen-presenting cell (Chapter 7). In addition to their nonspecific effector functions, these cells are crucial for the development of specific immune responses. With maturation, these cells enter the blood (Table 2.4), where they circulate into the tissues and organs.

Antigen-presenting cells

Cells that act as antigen-presenting cells (APC) include a diverse group of leukocytes such as monocytes, macrophages, dendritic cells and B cells. In addition, endothelial or epithelial cells can acquire antigen-presenting abilities after the upregulation of major histocompatibility complex (MHC) class II expression by various cytokines (see Chapter 5).

APC are found primarily in the solid lymphoid organs and in the skin. In most tissues the frequency of these cells varies between 0.1% and 1.0%. The specialized APC in the B-cell areas of the lymph nodes and spleen are termed follicular dendritic cells. They trap antigen-antibody complexes and thus play a key role in the generation and maintenance of memory B cells. These cells do not express class II molecules, but do have receptors for IgG and complement component C3b, Fc γ R (CD64) and CR1 (CD35), respectively. Antigen-presenting cells termed dendritic cells are abundant in the thymic medulla and play a role in the education (positive and negative selection) of thymocytes.

Dendritic cells residing in peripheral sites such as the skin, intestinal lamina propria, lung, genitourinary tract etc. are

Table 2.4 Normal distribution of white blood cells in the peripheral blood of adults and children.

Cell Type	Approximate percentage		Range of absolute counts (no./mm ³)	
	Adults	Children (0–2 yrs)	Adults	Children (0–2 yrs)
Monocytes	4–13		400–1000	
Dendritic cells	0.5–1	ND	30–170	ND
Granulocytes	35–73		2500–7500	1000–8500
Lymphocytes	15–52	34–75	1450–3600	3400–9000
As % of lymphocytes				
T cells	75–85	53–84	900–2500	2500–6200
CD4 cells	27–53	32–64	550–1500	1300–4300
CD8 cells	13–23	12–30	300–1000	500–2000
B cells	5–15	06–41	100–600	300–3000
NK cells	5–15	03–18	200–700	170–1100

* Not determined. Child data adapted from Shearer W, Rosenblatt H, Gelman R, et al. Lymphocyte subsets in healthy children from birth through 18 years of age: The pediatric AIDS Clinical Trials Group P1009 study. J Allergy Clin Immunol 2003; 12: 973–980.

typically immature. These cells are more phagocytic and express fewer MHC class I, MHC class II and costimulatory molecules. These immature dendritic cells take up antigens in tissues for subsequent presentation to T cells. During migration to the lymph nodes, dendritic cells undergo phenotypic and functional changes characterized by increased expression of MHC class I, MHC class II and costimulatory molecules (e.g., B7-1 [CD80] and B7-2 [CD86]), which react with ligands CD28 and CTLA-4 expressed by T cells.¹⁹

The predominant APC of the skin are the Langerhans' cells.²⁰ These are found in the epidermis and are characterized by rocket-shaped granules called Birbeck's granules. Upon migration from the skin, these cells deliver antigens entering the skin to the effector cells of the lymph nodes.

The immature tissue dendritic cells in peripheral tissues also engulf and process antigens. They leave the tissues and home to T-cell areas in the draining lymph nodes or spleen.²¹ At these sites they can directly present processed antigens to resting T cells to induce their proliferation and differentiation. These effector cells then home to the site of the antigenic assault. The key distinction between mature dendritic cells and macrophages in terms of antigen presentation is the ability of dendritic cells to activate resting T cells directly.

Monocytes–macrophages

Cells of the monocyte–macrophage lineage exist in blood (~10% of white blood cells) primarily as monocytes, large 10–18 μm cells with peanut-shaped, pale purple nuclei as determined by Wright's staining (Table 2.4). The cytoplasm, which is 30–40% of the cell, is light blue and has azurophilic granules that resemble ground glass. There also are numerous intracytoplasmic lysosomes. The cells have a number of characteristic cell surface molecules, including MHC class II molecules, CD14 (the receptor for lipopolysaccharide), and distinct Fc receptors (FcR) for immunoglobulin (Ig) (Chapter 21). The latter include Fc γ RI (or CD64), which has a high affinity for IgG, and Fc γ RII (or CD32), which is of medium affinity and binds to aggregated IgG. Fc γ RIII (or CD16) has low affinity for IgG and is associated with antibody-dependent cellular cytotoxicity (ADCC). It is expressed on macrophages, but not on blood monocytes. Monocytes and macrophages also express CD89, the Fc receptor for IgA.

Macrophages are more differentiated monocytes that reside in various tissues, including lung, liver and brain.²² Most cells of the monocyte–macrophage lineage adhere strongly to glass or plastic surfaces, a property often used to deplete or purify them from mixed cell populations. Many cells of this lineage phagocytose organisms or tumor cells *in vitro*. Cell surface receptors, including CD14, Fc γ receptors and CR1 (CD35), are important in opsonization and phagocytosis. Cells of this lineage also express MHC class II molecules and some express the low-affinity receptor for IgE (CD23). Other cell surface molecules include myeloid antigens CD13 (aminopeptidase N) and CD15 (Gal (1–4) or [Fuc (1–3)] GlcNAc) and the adhesion molecules CD68 and CD29 or CD49d (VLA-4). In addition to phagocytic and cytotoxic functions, these cells have receptors for various cytokines such as IL-4 and IFN- γ that can serve to regulate their function. Activated macrophages are also a major source of cytokines, including IFN, IL-1 and TNF, as well as complement proteins and prostaglandins.

Monocytes and macrophages arise from colony-forming unit granulocyte–monocyte (CFU-GM) progenitors that differentiate first into monoblasts, then promonocytes, and finally monocytes.²³ Mature monocytes

leave the bone marrow and circulate in the bloodstream until they enter tissues, where they develop into tissue macrophages (e.g., alveolar macrophages, Kupffer cells and microglial cells).

Several cytokines have been shown to participate in the development of monocytes and granulocytes. For example, SCF, IL-3, IL-6, IL-11 and GM-CSF have all been shown to promote the development of myeloid lineage cells from CD34⁺ stem cells, especially those in the early stages of differentiation. Another cytokine, M-CSF, acts at the later stages of development and is lineage specific, inducing maturation into macrophages.¹⁹

Dendritic cells

Dendritic cells are accessory cells that express high levels of MHC class II antigen and are potent inducers of primary T-cell responses. Except for the bone marrow, they are found in virtually all primary and secondary lymphoid tissues, as well as in skin, mucosa, and blood. Dendritic cells are derived from CD34⁺ MHC class II-negative precursors present in the bone marrow that also give rise to macrophages and granulocytes. GM-CSF and TNF- α are involved in the development of dendritic cells from their precursors in bone marrow.²⁴ Langerhans' cells are the immediate precursors of dendritic cells in the skin. After encountering antigen, Langerhans' cells migrate from the skin through afferent lymphatics and into draining lymph nodes, where they enter via the subcapsular sinus. Interdigitating dendritic cells, which present peptide antigens bound to MHC class II molecules to T cells in the lymph nodes and spleen, appear to derive from these Langerhans' cell immigrants. TNF- α also maintains the viability of Langerhans' cells in the skin and stimulates their migration. In Peyer's patches, immature dendritic cells occur in the dome region underneath the follicle-associated epithelium (FAE), where they actively endocytose antigens taken up by M cells in the FAE. More mature interdigitating dendritic cells are found in T-cell regions, where they appear to be the major APC type. These cells, like their counterparts in the lungs, induce T-helper type 2 immune responses. There are at least two types of dendritic cell: the DC1 type are bone marrow derived and found in lymphoid tissues. Plasmacytoid DCs or DC2 are high producers of IFN- α . Their derivation is unclear, but may be myeloid or lymphoid.^{25,26}

Polymorphonuclear granulocytes

Polymorphonuclear (PMN) granulocytes arise from progenitors that mature in the bone marrow. They are released into the blood as short-lived (2–3 days), essentially end-stage, cells. They constitute 65–75% of the white blood cells in the peripheral blood, are 10–20 μm in diameter, and have features such as a multilobed pyknotic nucleus characteristic of cells undergoing apoptosis (Table 2.4).²⁷ PMNs are also found in tissues and use the process of diapedesis to gain access from the blood. Granulocytes act as early soldiers in the response to stress, tissue damage or pathogen invasion. Because of their function in phagocytosis and killing, they possess granules whose unique staining characteristics are used to categorize the cells as neutrophils (Chapter 21), basophils (Chapter 22) or eosinophils (Chapter 23).

Neutrophils

Most circulating granulocytes are neutrophils (90%). Their granules are azurophilic and contain acid hydrolase, myeloperoxidase and lysozymes. These granules fuse with ingested organisms to form phagolysosomes,

which eventually kill the invading organism. In some cases there is extracellular release of granules after activation via the Fc receptors. Neutrophils express a number of myeloid antigens, including CD13, CD15, CD16 (FcγRIII) and CD89 (FcαR). In response to bacterial infection there is typically an increase in the number of circulating granulocytes. This often includes the release of immature granulocytes, called band or stab cells, from the bone marrow. In a mild infection, both the number and function of neutrophils are increased. This is associated with a delay in apoptosis. With a more severe infection there may actually be impairment of function owing to the release of immature cells.

Neutrophils derive from CFU-GM progenitor cells. These give rise to myeloblasts, which in turn differentiate into promyelocytes, myelocytes, and finally mature neutrophils. The cytokines SCF, IL-3, IL-6, IL-11 and GM-CSF promote the growth and development of neutrophil precursors, whereas certain cytokines are important for differentiation of CFU-GM progenitors into mature neutrophils.²⁸ For example, G-CSF induces maturation of neutrophil precursors into mature neutrophils. IL-4 enhances neutrophil differentiation induced by G-CSF, while at the same time inhibiting the development of macrophages induced by IL-3 and M-CSF.

Eosinophils

Eosinophils typically comprise 2–5% of the white cells in the blood. They exhibit a unique form of diurnal variation because the peak of production occurs at night, perhaps because glucocorticoids are lower at night. Eosinophils are capable of phagocytosis followed by killing, although this is not their main function. The granules in eosinophils are much larger than in neutrophils and are actually membrane-bound organelles. The crystalloid core of the granules contains a large amount of major basic protein (MBP), which can neutralize heparin and is toxic. During degranulation, the granules fuse to the plasma membrane and their contents are released into the extracellular space. Organisms that are too large to be phagocytosed, such as parasites, can be exposed to cell toxins by this mechanism. For example, MBP can damage schistosomes *in vivo*. However, tissue damage is kept to a minimum because the MBP is confined to a small area between the eosinophil and the schistosome. Eosinophils also release products that counteract the effects of mast cell mediators.

Eosinophils derive from a progenitor (CFU-Eo) that progresses through development stages similar to those of neutrophils.²⁹ These stages begin with an eosinophilic myeloblast, followed by an eosinophilic promyelocyte, a myelocyte, and finally a mature eosinophil. Three cytokines are important in the development of eosinophils: GM-CSF, IL-3 and IL-5. GM-CSF and IL-3 promote eosinophil growth and differentiation; SCF also has an effect on eosinophil function (Chapter 23). IL-5 has more lineage-specific effects on eosinophil differentiation, although it also affects some subsets of T and B cells. IL-5 inhibits eosinophil differentiation, as well as apoptosis.

Basophils and mast cells

Basophils represent less than 1% of the cells in the peripheral circulation, and have characteristic large, deep-purple granules. Mast cells, found only in tissues, are much larger than peripheral blood basophils. The granules are less abundant and the nucleus is more prominent. There are two different types of mast cell, designated mucosal or connective tissue

depending on their location.³⁰ Mucosal mast cells require T cells for their proliferation, whereas connective tissue mast cells do not. Both types have granules that contain effector molecules. After degranulation, which is effected by cross-linkage of cell surface IgE bound to cells via the high-affinity receptor for IgE, the basophils–mast cells release heparin, histamine and other effector substances to mediate an immediate allergic attack (Chapter 22).

Basophils and mast cells share a number of phenotypic and functional features that suggest they are derived from a common precursor. They both contain basophilic-staining cytoplasmic granules; they both express the high-affinity IgE receptor (FcεRI); and they both release a number of similar chemical mediators that participate in immune and inflammatory responses, particularly anaphylaxis. However, basophils and mast cells have some distinct morphologic and functional characteristics that suggest they represent distinct lineages of cells, rather than cells at different stages within the same lineage. Basophils mature from a progenitor (CFU-BM) into basophilic myeloblasts, then basophilic promyelocytes, myelocytes, and finally mature basophils. Less is known about the stages of mast cell development, although they are probably derived from the same CFU-BM progenitor as basophils.

In human basophils and mast cells, SCF induces the most consistent effects on growth and differentiation. Recently it has been shown that IL-3, as well as SCF, is important for intestinal mast cell differentiation. This probably explains why T cells are needed for their development.³¹ In contrast to mouse mast cells, IL-4 and IL-9 do not appear to stimulate the development of human mast cells from progenitors. However, IL-9 does act in synergy with SCF to enhance the growth of mast cells. Additional cytokines that affect basophil growth include nerve growth factor and GM-CSF or TGF-β, and IL-5 for basophil differentiation.

Platelets and erythrocytes

Hematopoietic stem cells also give rise to platelets and erythrocytes. These cells derive from CFU-GEMM progenitors, which in turn differentiate into burst-forming units for megakaryocytes (BFU-MEG) in the case of platelets, and burst-forming units for erythrocytes (BFU-E) in the case of erythrocytes. The BFU-MEG subsequently differentiate into CFU-MEG, promegakaryoblasts, megakaryoblasts, megakaryocytes, and finally platelets.³² Several cytokines, particularly thrombospondin, IL-1, IL-3, GM-CSF, IL-6, IL-11 and LIF, affect the growth and differentiation of platelets. In the case of erythrocytes, BFU-E differentiate into CFU-E, then pronormoblasts, basophilic normoblasts, polychromatophilic normoblasts, orthochromic normoblasts, reticulocytes, and finally erythrocytes.³³ Again, several cytokines, notably GM-CSF, SCF, IL-9, thrombospondin and erythropoietin, regulate erythrocyte development.

Lymphocytes

Lymphocytes, the central cell type of the specific immune system, represent about 25% of white cells in the blood (Table 2.4). Small lymphocytes are 7–10 μm in diameter, are characterized by a nucleus that stains dark purple with Wright's stain, and contain very little cytoplasm. Large granular lymphocytes are 10–12 μm in diameter and contain more cytoplasm and scattered granules. There are three types of lymphocyte that circulate in the peripheral blood: T, B and NK cells, representing

respectively about 80%, 10% and 10% of total lymphocytes (Chapters 8, 9 and 18). In the thymus most of the lymphocytes (90%) are T cells; however, in the spleen and lymph nodes only about 30–40% are T cells. The preponderant lymphocytes in these locations are B cells (60–70%).^{34,35}

T lymphocytes

T lymphocytes arise from lymphocyte progenitors in the bone marrow which are committed to the T-cell lineage before homing to the thymus. In the early stages of embryogenesis, T-cell precursors to migrate into the thymus in waves.^{36,37} Associated with this migration is the developing ability of thymic education elements, epithelial cells, and dendritic cells to select appropriate T cells.³⁸ In the thymus, T cells rearrange their specific antigen receptors (TCR) and then express CD3 along with the TCR on their surface (Chapter 9). Resting T cells in the blood are typically 7–10 μm in diameter and are agranular, except for the presence of a structure termed a Gall body, not found in B cells (Table 2.4). The Gall body is a cluster of primary lysosomes associated with a lipid droplet. A minority of T cells in the blood (about 20%), are of the large granular type, meaning that they are 10–12 μm in diameter and contain primarily lysosomes, which are dispersed in the cytoplasm. Golgi apparatus also are found. The preponderant form of the TCR, found on about 95% of circulating T cells, consists of α and β chains ($\alpha\beta\text{TCR}^+$).³⁹ Some CD3⁺ cells do not express either CD4 or CD8 and are characterized by having an alternative TCR of composed of γ and δ chains ($\gamma\delta\text{TCR}^+$). Further differentiation in the thymus occurs from CD3⁺, CD4⁺ and CD8⁺ cells to cells expressing either CD4 or CD8 but not both (Chapter 9). These mature cells then circulate in the peripheral blood at ratio of about 2:1 (CD4:CD8) and populate the lymph nodes, spleen and other secondary lymphoid tissues.

T-cell progenitors, which are CD7⁺, are believed to arise in the bone marrow from a multipotential lymphoid stem cell. After migration to the thymus, the CD7⁺ T cells give rise to a population of CD34⁺, CD3⁺, CD4⁺, and CD8⁺ T-cell precursors, which undergo further differentiation into mature T cells. Cytokines produced by thymic epithelial cells, for example IL-1 and soluble CD23, promote the differentiation of these precursors into CD2⁺, CD3⁺ thymocytes (Table 2.3). IL-7 induces the proliferation of CD3⁺ double-negative (CD4[−] CD8[−]) thymocytes, even in the absence of comitogenic stimulation. IL-7 is absolutely required for human T-cell development.⁴⁰ IL-2 and IL-4 demonstrate complex effects on thymocyte development. Both appear capable not only of promoting the development of prothymocytes but also of antagonizing their development. IL-6 acts as a costimulator of IL-1- or IL-2-induced proliferation of double-negative (DN) thymocytes and can stimulate the proliferation of mature, cortisone-resistant thymocytes alone. Once T cells leave the thymus, a variety of cytokines affect their growth and differentiation.

Subpopulations of T cells

T cells can be divided into subsets based on their surface expression of CD4 and CD8, as well as by their function in the immune response. CD4 and CD8 T cells were originally characterized by expression of the respective antigen and association with functional ability. For example, human T cells expressing CD4 provide help for antibody synthesis, whereas cells expressing CD8 were found to develop into cytotoxic T cells. These functional distinctions are less clear today; instead, the

distinction between cells expressing CD4 or CD8 involves which antigen-presenting molecule is used for TCR interaction. Thus, CD4 T cells recognize antigen in the context of MHC class II molecules, and CD8 T cells recognize antigen presented by class I molecules (Chapter 5).

T-helper (Th) cells mature in response to foreign antigens. Their function is dependent on the production of cytokine modules, which characterize them as Th type 1 (Th1), Th2 or Th17.⁴¹ The precursor Th cell first differentiates into a Th0 cell producing interferon- γ (IFN- γ) and IL-4. The cytokine environment subsequently determines whether Th1 or Th2 cells predominate. Th1 cells produce primarily IFN- γ , IL-2 and TNF- α , and are important in cell-mediated immunity to intracellular pathogens, such as the tubercle bacillus. Th2 cells produce predominantly IL-4, IL-5, IL-6, IL-10 and IL-13, as well as IL-2, and predominate in immediate or allergic type 1 hypersensitivity. Other populations of CD4 T cells can develop and rely on IL-23 or IL-12 action upon the cells.⁴² If T cells are exposed to IFN- γ , they upregulate both IL-12R and IL-23R, which then produce either conventional Th1 cells or another subset, Th17, that produces IL-17 and which has been associated with autoimmunity. Conversely, IL-17-producing CD4 cells also result from the direct action of IL-23 without IL-12 involvement. It is likely that there will be other epigenetically altered T cells that allow diversity of function during an immune response.

A minor subpopulation (<5%) of CD3⁺ cells in the peripheral blood express $\gamma\delta$ TCR molecules. Most of these cells do not express CD4 or CD8. However, some intraepithelial lymphocytes that express $\gamma\delta$ TCR also express CD8 $\alpha\alpha$ homodimers, rather than conventional CD8 $\alpha\beta$ heterodimers. These cells, which are thymus independent, are thought to be involved in the initial response to bacterial antigens presented in the mucosal epithelium. Another minor subpopulation of T cells, NKT cells, can be CD4 or CD8 expressing a single V α chain, V α 24, that recognizes glycolipids in the context of CD1a, not MHC.^{43,44} The final minor subset are regulatory T cells, which occur naturally and can be induced *in vitro*. They are CD4⁺ and express high levels of CD25 and the transcription factor foxp3. These cells are important in regulatory immune responses, are reduced in autoimmunity and increased in cancer.^{45,46}

B cells and plasma cells

B cells represent 5–10% of the lymphocytes found in the blood (Table 2.4). They are typically 7–10 μm in diameter and lack Gall bodies and granules. The cytoplasm is characterized by scattered ribosomes and isolated rough endoplasmic reticulum (RER). The Golgi is not prominent, unless B cells are activated. B cells express cell membrane immunoglobulin (mIg), the majority expressing both IgM and IgD.⁴⁷ A small minority of B cells expresses surface IgG or IgA. Plasma cells (10–15 μm) are not normally found in the blood. They display an eccentric nucleus and a basophilic cytoplasm with a well-developed Golgi. The plasma cell displays parallel arrays of expanded RER that contains Ig.

A number of other cell surface molecules are found on B cells (Chapter 8), including CD19, CD20, CD40, CD79, MHC class II, Fc γ RII receptors (CD32) and complement receptors C3b (CR1a; CD35) and C3d (CR2a; CD21). Like T cells, which surround the TCR with activation effector molecules, termed CD3, the B-cell Ig also has a B-cell receptor complex consisting of CD19, CD21 and CD81 (Chapter 4). Upon activation and cross-linking of surface Ig by specific antigen, B cells undergo proliferation and differentiation to produce plasma cells. Plasma cells are nondividing, specialized cells whose function is to secrete Ig. They lose the expression of

mIg and MHC class II molecules. B-cell proliferation and differentiation processes take place in the germinal centers of the lymph nodes.

Several cytokines influence the development of B lymphocytes. *In vitro* studies of cytokines involved in the development of early B-cell progenitors have demonstrated that combinations of SCF (but not IL-3) with IL-6, IL-11 or G-CSF can maintain B-lymphoid potential.⁴⁸ Stromal cell-dependent differentiation of fetal pro-B cells occurs in conjunction with Flk-2/flt-3 ligand.

IL-4 has a variety of important effects on B-cell growth and differentiation. Low doses of IL-4 induce pre-B cells to differentiate into B cells expressing surface IgM, whereas higher doses of IL-4 inhibit differentiation into B cells. IL-4 has additional effects on mature B cells, including an increase in expression of MHC class II, CD23 and CD40 molecules; activation with progression to the G₁ stage of the cell cycle; enhancement of proliferation after stimulation through the Ig receptor; and induction of immunoglobulin class switch in human to IgG₄ and IgE (IgG₁ and IgE in mouse). IL-13, which is closely related to IL-4, has many similar effects on B cells.

Other cytokines, such as IL-2, IL-5, IL-6, IL-11 and nerve growth factor (NGF), act on mature B cells and can either enhance their proliferation or promote their differentiation into immunoglobulin-secreting cells. In addition, IL-10 enhances the viability of B cells *in vitro*, increases MHC class II expression, and augments the proliferation and differentiation of B cells after stimulation through the Ig receptor or CD40. TGF- β_1 is a major switch factor for IgA. This cytokine induces human B cells triggered with mitogen to switch to both IgA₁ and IgA₂. SDF-1 (stromal cell-derived factor) has been shown to attract early-stage B-cell precursors and is a likely mechanism whereby B cells form islands in the bone marrow.¹⁸ There are at least two populations of B cells: those that express CD5 (B-1) and are found in the follicular mantle, and those that do not (B-2), which are primarily found in lymphoid follicles. The B-1 lineage produce natural antibodies, primarily IgM, and are the first to develop during gestation.^{49, 50}

Natural killer cells

NK cells comprise the third major lymphocyte subset, i.e., 10–15% of circulating lymphocytes (Table 2.4). These cells are usually larger than typical lymphocytes (10–12 μ m) and display less nuclear material and more cytoplasm than do small lymphocytes. They possess electron-dense peroxidase-negative granules and a well developed Golgi apparatus. Functional NK cells can be found in the fetal liver as early as 6 weeks' gestation. These fetal NK cells express cytoplasmic CD3 proteins, but exhibit no TCR rearrangements. Evidence suggests that an Fc γ receptor-positive cell that does not express lineage-specific markers (LIN⁻) exists in the fetal mouse thymus, where it normally gives rise to T cells. However, if removed from the thymus, the cells develop into CD3⁻ NK cells. Such CD3⁻ cells with variable CD16 expression exist in human thymocyte populations and can be induced to proliferate, to express NK-associated antigens, and to exhibit NK cell function *in vitro*. These cells also express substantial levels of CD3 δ and CD3 ϵ in the cytoplasm.⁵¹

Mature NK cells do not express conventional antigen receptors, such as TCR or Ig, and the genes for these receptors remain unrearranged. Some express Fc γ RIII (CD16) and others express CD56, an adhesion molecule. NK cells, like T cells, also express the CD2 molecule. NK cells express the β chain of the IL-2 receptor, CD122, which allows resting NK cells to

respond directly to IL-2. The function of NK cells is to provide nonspecific cytotoxic activity towards virally infected cells and tumor cells (Chapter 18). NK cells also can kill specifically when they are provided an antibody. This death delivery mechanism, known as antibody-dependent cellular cytotoxicity (ADCC), occurs via binding of the antibody to the Fc γ receptor CD16. After activation, NK cells produce cytokines, such as IFN- γ , that can affect the proliferation and differentiation of other cell types. Recent evidence suggests several possible recognition molecules on human NK cells, some activating, some inhibiting, and some acting as receptors for MHC class I molecules.

The ontogeny of NK cells is now better understood. Although they express a number of membrane antigens in common with T cells and share functional properties with some T-cell subsets, suggesting a common origin, NK cells are found in fetuses before the development of T cells or the thymus. In addition, NK cells appear to develop normally in nude, athymic mice. Moreover, NK cells probably develop extrathymically, and recent data suggest that they can develop from stem cells in the lymph nodes. NK cells arise from triple-negative (CD3⁻CD4⁻CD8⁻) precursors that are CD56⁺, but do not express CD34 or CD5. T cells, on the other hand, develop from 'triple-negative' precursors that are CD34⁺CD5⁺CD56⁺. It is likely that T cells and NK cells arise from a common 'triple-negative' precursor with the phenotype CD7⁺CD34⁺CD5⁺CD56⁺.

Recent evidence suggests that the cytokine receptor that determines lineage specificity is the α chain of the IL-2 receptor, CD25. Once CD25 is upregulated, the cell is destined to become a T cell. The cytokines most important in the early development of NK cells are IL-15 and IL-7. Flt ligand and *c-kit* also facilitate NK cell expansion. Several cytokines have been shown to promote the growth and differentiation of mature NK cells. IL-2, the first cytokine shown to have effects on NK cells, induces the proliferation and activation of NK cells. This probably occurs via the IL-2 receptor β chain (CD122), as NK cells do not express CD25. IL-2 also induces the growth of NK cells from precursors in bone marrow cultures. Both IL-7 and IL-12, also known as NK-cell stimulatory factor, have been shown to activate NK cells. Although IL-4 inhibits the effects of IL-2 or IL-7 on NK cells, it acts synergistically with IL-12 to induce proliferation of CD56⁺ cells. IL-6, despite having no effect by itself, enhances NK cell activity in thymocytes cultured with IL-2. Finally, IL-15 is also involved in signalling NK cells for survival.⁵²

KEY CONCEPTS

TISSUES OF THE IMMUNE SYSTEM

- >> The immune system consists of central locations of immune cell production and differentiation, and dispersed organs, where encounter with and response to antigens occur.
- >> B cells and T cells develop in the bone marrow and thymus, respectively.
- >> The mucosal surfaces and skin provide the primary access for foreign antigens to cells of the immune system, where they first interact primarily with antigen-presenting cells.
- >> The secondary lymph organs, which include the spleen, lymph nodes, tonsils and Peyer's patches, are where immune reactions occur.

MAJOR LYMPHOID ORGANS

The primary lymphoid organs are sites where lymphocytes differentiate from stem cells and proliferate and mature into effector cells. From birth to old age, these functions are carried out only in the bone marrow and the thymus.

BONE MARROW

The bone marrow provides the environment necessary for the development of most of the white blood cells of the body (Fig. 2.2). At birth, most bone cavities are filled with actively dividing blood-forming

elements known as 'red' marrow. Beginning at about the age of 3–4 years, however, the tibia and femur become filled with fat cells, which limits their role in hematopoietic development. The ribs, sternum, iliac crest and vertebrae remain 30–50% cellular and continue to produce hematopoietic cells throughout life.¹ Three main components are found in the bone marrow: the blood vessels, the cells, and the extracellular matrix. The production of cells from HSC occurs in areas separated by vascular sinuses. The walls of the surrounding sinus contain a layer of endothelial cells with endocytic and adhesive properties. These specialized endothelial cells of the sinuses probably produce type IV collagen and laminin for structural support. These cells also elaborate colony-stimulating factors and IL-6. The outer wall of the sinus is irregularly covered with reticular cells, which branch into areas where cells are developing and provide anchors for those cells by producing reticular fibers. Megakaryocytes lie against this wall, touching the endothelial cells. A functional unit of marrow called a spheroid contains adipocytes, stromal cell types and macrophages. These reticular cell networks compartmentalize the developing progenitor cells into separate microenvironments called hematons.

The distribution of stem and progenitor cells across the radial axis of the bone suggests that the HSC are next to the bone surface, whereas the more mature progenitor cells are nearer the central venous sinus. This distribution serves to facilitate the eventual release of mature cells. The production of new progenitor cells from stem cells occurs as a result of interactions between stem cells and stromal cells. Given the right stimulus, most of the progeny proliferate and differentiate further, which may result in migration from the bone marrow. In migrating, the cells become detached from the stromal elements and progress toward the central sinus. Control of hematopoiesis is regulated by both positive and negative cytokines and by up- and downregulation of various adhesion molecules in committed progenitor cells. The molecules involved include the fibronectin receptor, glycoproteins IIb and IIIa, ICAM-1 (CD54), LFA-1 (CD11, CD18), LFA-3 (CD58), CD2 and CD44. Adhesion molecules on stromal cell surfaces include fibronectin, laminin, ICAM-1 (CD54), types I, III and IV collagen, and N-CAM. The most clearly established role for adhesion molecules involves fibronectin, which allows erythroid precursors to bind to stromal cells and thus facilitates progression from erythroblast to reticulocyte.

The accessory cell populations found in the bone marrow regulate many aspects of hematopoiesis, both positively and negatively. The upregulation of the growth of the earliest progenitor cells is mediated by cytokines. For example, macrophages produce IL-1, which then induces stromal cells to express growth factors such as GM-CSF, IL-6 and IL-11. However, downregulation can occur at any stage. For example, T cells can regulate hematopoiesis by producing factors that act on early erythroid progenitor cells, BFU-E. Later progenitors, CFU-E, are then more fully differentiated by erythropoietin. By contrast, activated T cells produce factors that can suppress BFU-E and CFU-E *in vitro*.

Cells in the bone marrow were originally characterized by morphology. The predominant types are those of the myeloid lineage, which account for about 50–70% of the cells (Fig. 2.3). Red blood cell precursors represent from 15% to 40% of the total cells. Other lineages exist in lower proportions (<5%). With the advent of cell surface antigen markers and flow cytometry, a more precise delineation could be made. Thus, of the mature leukocytes in the bone marrow, approximately 70% are CD3⁺, CD14⁺, CD20⁺ or CD11b⁺. These are designated as Lin⁺. Of the Lin[−] cells, about 6% are CD33⁺ and primarily of myeloid lineage. A Lin[−]CD71⁺ population represents about 18% of the total and is preponderantly of the red blood cell lineage.

Fig. 2.2 Structure of the bone marrow, showing islands of erythropoiesis, granulopoiesis and scattered lymphocytes.

Fig. 2.3 Flow cytogram of normal human bone marrow based on CD45 expression and side scatter. Most of the major hematopoietic populations can be delineated. In this example 1.5% are red blood cell precursors (NRBC), 1.5% are lymphoblasts, 3.0% are mature lymphocytes (Lymphs), 3.0% are monocytes (Monos), 4.0% are myeloblasts, 45% are segmented neutrophils (Seg neutro) and 42% are immature myeloid cells (Imm myel).

Fig. 2.4 Structure of the thymus, showing pre-T cells entering from the bone marrow (BM). Positive selection occurs on thymic epithelial cells; negative selection probably occurs during interactions with corticomedullary dendritic cells. This may explain why single-positive CD4 or CD8 cells are found primarily in the medulla. Nurse cells appear to remove negatively selected cells. Hassall's corpuscles are specialized cells producing thymic growth factors.

THYMUS

The thymus is located in the mediastinum and below the sternum. This bilobed organ develops from the third and fourth pharyngeal pouches and is endodermal in origin. It is organized into a loose lobular structure, with areas in each lobe consisting of a cortex of rapidly dividing cells and a medullary area that contains fewer, but more mature, T cells (Figs 2.4, 2.5). This arrangement has long suggested a scenario for differentiation where cells progress from the cortex to the medullary area. Nonlymphocyte cells play very important site-specific roles in the thymic development of T cells. Epithelial cells are scattered throughout the thymus. Depending on their location, they are known as nurse cells, cortical epithelial cells or medullary epithelial cells. Macrophage-type cells and interdigitating cells that are bone-marrow derived can be found at the junction between cortex and medulla. These also play an important role in T-cell selection.

It is thought that enlarged, activated T-cell precursors from the bone marrow originally colonize the subcapsular region of each lobe. These are actively proliferating and can self-renew. Selection begins when their progeny encounter MHC class II antigen-bearing cortical epithelial cells. A further education process probably occurs by interaction with macrophage-like cells found at the corticomedullary junction and in the medulla.

Thymic nurse cells, which also are found in the cortex, were originally thought to contribute to the thymic education of T cells. Because large numbers of thymic cells (50–200) can be found inside each nurse cell, it was believed that these structures provided an environment where selection and expansion could occur. However, recent evidence suggests that 'nurse' may be a misnomer because, rather than aiding in their development, the nurse cells appear to dispose of developing T cells that are selected against and which are dying by apoptosis. Nurse cells are very busy, because about 90% of cortical T cells die at this stage.

A structure known as Hassall's corpuscle, which consists of concentric whorls of epithelial cells, is found in the medulla, but its function is

unclear. These medullary epithelial cells contain secretory granules, and it is thought that this network of cells may be active in the production of thymic hormones. In the fetus these bundles of cells are widely scattered, but they become larger as the thymus matures. The center cells eventually become keratinized and die.

The thymic differentiation process (Chapter 9) involves the rearrangement of functional TCR, surface expression of CD3, and a process of positive and negative selection that allows only a small percentage of putative T cells to survive. Pre-T cells in the thymus express CD2, CD5 and CD7, as well as activation antigens such as CD38 and the transferrin receptor (CD71). Pre-T cells express intracytoplasmic CD3 and exhibit rearrangements in the TCR- β chain. Successful rearrangement of TCR- α allows the cell to progress to the next stage of development, with functional TCR and CD3 on the cell surface.³⁸ These later-stage cells represent most of the cells in the thymus (85%). These immature cells express both CD4 and CD8 on their surface, as well as CD1. CD69, an activation marker, is upregulated at this 'double-positive' stage. CD69 continues to be expressed until the cell reaches the single-positive stage, where it will express either CD4 or CD8, but not both. T cells are CD45RO⁺ at the double-positive stage and all the way to the single-positive stage. Prior to leaving the thymus, CD45RO is downregulated and CD45RA appears. The most mature thymic cells are characterized by loss of CD1 expression and loss of CD4 or CD8 expression. Most of these mature cells are also negative for activation molecules (CD38 and CD71). However, they acquire an adhesion molecule called CD44, which is necessary for homing. Upon completion of this thymic selection and education process, mature CD4 or CD8 T cells leave the thymus and enter the peripheral circulation via the postcapillary venules at the corticomedullary junction.

Fig. 2.5 Human thymus showing cortex and medullary areas. Cortical thymocytes are stained with an anti-CD1 antibody. Most medullary T cells do not express CD1.

After birth and during childhood the thymus continues to grow and select and educate T cells. This process is probably necessary to develop a fully normal repertoire. Prior to puberty, however, the thymus begins to involute. The rapidly dividing cortex is the first to atrophy, leaving medullary areas intact. The sensitivity of cortical thymocytes to hormone-induced death probably accounts for the involution, although there is evidence that human thymocytes are less sensitive to glucocorticosteroids than are murine thymocytes. However, an increase in steroids is known to reduce immature thymocyte numbers and enhance thymus involution. Recent evidence suggests that active TCR rearrangements, and hence T-cell development, continue to occur in the adult thymus, albeit at a lower level than during childhood.

DEVELOPMENT OF HEMATOPOIETIC AND LYMPHOID CELLS

Although most of the key steps during the growth and development of hematopoietic and lymphoid cells occur in the bone marrow and thymus, additional maturation steps occur after the cells leave those tissues. For example, monocytes and dendritic cell precursors migrate from blood vessels into tissues, where they mature into macrophages and dendritic cells, respectively. Likewise, mast cells and eosinophils undergo further differentiation in resident tissues. After leaving the bone marrow and thymus, B and T cells undergo further maturation and memory cell development in secondary lymphoid organs. Some T cells, particularly the $\gamma\delta$ T cells residing in mucosal epithelium, may develop extrathymically.

SECONDARY LYMPHOID ORGANS

Secondary lymphoid organs are sites where mature lymphocytes reside and where immune responses are generated. Secondary lymphoid organs are part of either the systemic immune system or the mucosal immune system. The systemic immune system includes the spleen and lymph nodes and functions to protect the body from antigens present in the lymphatic drainage and circulating in the bloodstream. The mucosal immune system responds to antigens that enter through mucosal epithelium and plays an important role in the inductive phase of the immune response. Each mucosal immune system consists of organized secondary lymphoid structures, termed mucosa-associated lymphoreticular tissue (MALT), at which inductive immune responses occur, and more diffuse tissues such as the exocrine glands and lamina propria, in which effector immune responses occur. Immune responses in the mucosal immune system are initiated in the MALT, where naïve T and B cells encounter antigen, become activated, exit the tissue via efferent lymphatics, and migrate to the mesenteric lymph nodes, then into the thoracic duct and finally to the bloodstream. The cells then home to the effector sites, particularly the lamina propria of various mucosal tissues. The intraepithelial lymphocytes contained within the epithelium of mucosa and the lamina propria located immediately beneath the epithelium are the two components of the mucosal immune system responsible for carrying out effector functions (Fig. 2.6). They occur diffusely in mucosal tissues and lack the well-defined structure of the organized mucosal immune system. The ability of mucosal immune cells to circulate has led to the concept of a common mucosal immune system, so that induction of an immune response against a particular antigen leads to dissemination of lymphocytes to other mucosal tissues. Lastly, although not a systemic or mucosal lymphoid organ per se, the skin is a specialized secondary immune organ involved in the induction of immune responses.

SYSTEMIC IMMUNE SYSTEM: SPLEEN

The spleen is surrounded by a capsule of fibrous tissue with many trabeculae traversing from the capsule into the tissue of the spleen. These trabeculae branch and anastomose, forming a complex framework of lobules. Splenic blood vessels enter and exit through the hilum of the spleen and branch into smaller vessels within the trabeculae. Splenic tissue is supported by a fine network of reticular cells and fibers, called the reticulum, which connects

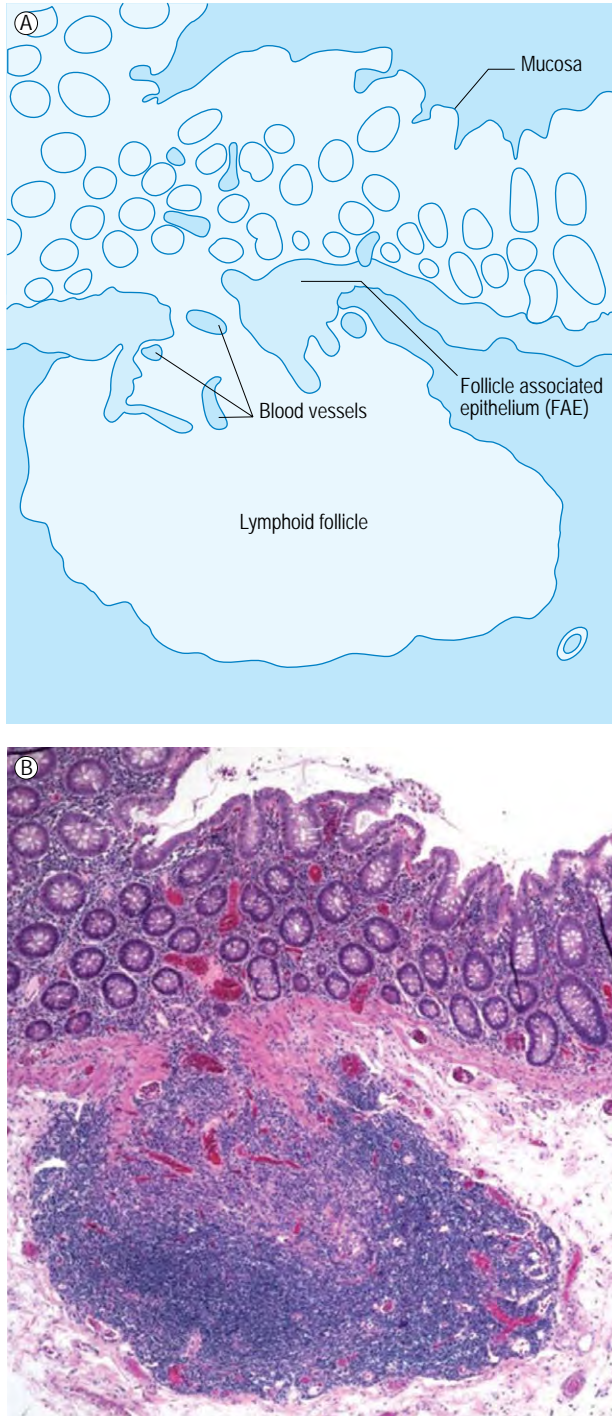

Fig. 2.6 Lymphoid follicles in the human large intestine. FAE, follicle-associated epithelium.

and supports the trabeculae, blood vessels, and capsule. The lobules of the spleen can be functionally divided into two compartments, the red pulp and the white pulp. The largest compartment is the red pulp, which contains numerous venous sinuses situated between arteries and veins. Blood is filtered through these sinuses, which contain many macrophages that phagocytose senescent red and white blood cells, bacteria, and other particulate material. Other leukocytes are found in the red pulp, including neutrophils, eosinophils, and lymphocytes, particularly plasma cells.⁵³

The white pulp consists of lymphoid tissue surrounding central arterioles, which are branches of trabecular arteries. This lymphoid tissue contains a T cell-predominant area immediately surrounding a central arteriole, the so-called periaarteriolar lymphoid sheath (PALS), which contains both CD4 and CD8 T cells. It is punctuated at intervals by B cell-predominant areas, follicles or so-called malpighian corpuscles. These B cell-predominant areas contain primary and secondary follicles. Primary follicles consist of only a mantle zone, without germinal centers, whereas secondary follicles contain an inner germinal center in addition to the outer mantle zone (Fig. 2.7). Within the mantle zone are predominantly resting B cells, which express surface IgM/IgD and CD23 (FcεRII). Germinal centers form in response to antigenic stimulation. It is within germinal centers that immunoglobulin class switch, affinity maturation through somatic mutation, and the development of memory B cells occur. Germinal centers are more prevalent at younger ages and diminish with aging. CD4 T cells play a key role in B-cell responses through CD40L interactions. The signaling that occurs through this interaction is central to the process of B-cell activation and the induction of class switching. In addition to activated B cells and CD4 T cells, the germinal center contains follicular dendritic cells (FDC) and macrophages.

At the interface between white pulp and red pulp is a region known as the marginal zone, that receives blood from branches of central arterioles opening into this region. It contains T cells, as well as particular subsets of macrophages and B cells. The marginal zone B cells (MZB), distinct from follicular B cells, express surface IgM but only low levels of IgD and no CD23. The function of the marginal zone involves the initial encounter of T cells and B cells with antigen from blood entering through branches of the central arteriole. Antigen presentation is enhanced by MZB cells, which are important in T cell-independent responses.

SYSTEMIC IMMUNE SYSTEM: LYMPH NODES AND LYMPHATICS

Lymph nodes occur as chains or groups located along lymphatic vessels. Lymph nodes exist in two major groups: those that drain the skin and superficial tissues (e.g., cervical, axillary, or inguinal lymph nodes), and those that drain the mucosal and deep tissues of the body (e.g., mesenteric, mediastinal, and periaortic lymph nodes). Lymph nodes are oval structures with an indentation at the region of a hilus, where blood vessels enter and leave the node (Fig. 2.8). A lymph node is surrounded by a fibrous capsule contiguous with trabeculae traversing the node. Blood vessels and nerves, which enter through the hilus, branch through these trabeculae to the various parts of the node. Immediately beneath the capsule is a subcapsular (marginal) sinus. Afferent lymph vessels enter into this sinus opposite the hilus. Dendritic cells process antigen encountered in the skin and migrate into lymph nodes from afferent lymphatics through the subcapsular sinus and into the lymph node. Lymph nodes vary in size, from barely visible in an unstimulated state to several centimeters in size when undergoing an active immune response.

Fig. 2.7 Human spleen showing a periarteriolar lymphoid sheath and germinal center.

Fig. 2.8 Human lymph node showing cortex, medullary areas and germinal centers.

A lymph node is divided into two major regions, the cortex and the medulla. The cortex contains numerous primary and secondary lymphoid follicles, each approximately 0.5 mm in diameter, similar to those in the spleen. Surrounding the lymphoid follicles in the cortex is the paracortical region, which contains mostly T cells along with some macrophages and dendritic cells. Both CD4 and CD8 T cells are present in this region, as are macrophages and B cells. The accessory cells, such as interdigitating dendritic cells, present peptide antigens in association with MHC molecules to the TCR on T cells, resulting in activation of the T cells. Additional accessory molecules (e.g., B7 [CD80] or LFA-3 [CD58]) on the accessory cell and their ligands (CD28 or CD2, respectively) on the T cell provide important costimulatory signals required for activation of the T cell. Other surface antigens, particularly adhesion molecules such

as LFA-1 (CD18) and ICAM-1 (CD54), are involved in stabilizing cellular interactions, as well as providing additional signals between cells.

In the center of the lymph node, beneath the cortex, lies the medulla, which is divided into medullary cords. Surrounding the medullary cords are medullary sinuses that drain into the hilus. B and T cells migrate from the follicles and paracortical region to the medulla. Medullary cords contain T cells, B cells and macrophages, as well as a large number of plasma cells, which produce immunoglobulin that drains into medullary sinuses emptying into the hilus. Efferent lymphatic vessels leave the hilus carrying antibodies, as well as mature B and T cells that migrate to other tissues and act as memory B and T cells during subsequent immune responses. The lymphatic vessel system serves to carry lymphocytes derived from various tissue spaces through the network of lymph nodes, eventually to the thoracic duct. This material is then drawn into the left subclavian vein and back into the circulation. By this mechanism, lymphocytes are circulated throughout the body.

MUCOSAL IMMUNE SYSTEM: GASTROINTESTINAL TRACT

The organized MALT of the gastrointestinal system is termed the gut-associated lymphoreticular tissue (GALT) and is comprised of Peyer's patches, cecal and rectal patches, and isolated lymphoid follicles (Chapter 19). Isolated lymphoid follicles and cecal and rectal patches are found throughout the lamina propria and are similar to an individual follicle of a Peyer's patch. Peyer's patches consist of variably sized aggregates of closely associated lymphoid follicles located in the intestinal lamina propria, occurring predominantly in the ileum⁵⁴ (Fig. 2.9). Although these structures arise during fetal life, their full development, with follicles containing germinal centers, does not occur until several weeks after birth, presumably in response to antigenic stimulation. Their number and size increase until puberty and decline thereafter. Peyer's patches and lymphoid follicles have a structural organization that belies their function of presenting antigen from the intestinal lumen to T and B cells. The epithelium overlying lymphoid follicles and Peyer's patches – that is, the follicular associated epithelium (FAE) – has a distinct structure. It lacks villi and contains very few goblet cells. Particulate antigen uptake via pinocytosis occurs in the FAE through specialized epithelial cells called M cells. The FAE expresses MHC class II antigens, with the exception of M cells; however, it does not express the polymeric immunoglobulin receptor (secretory component) required for secretion of IgA, which is expressed by crypt epithelial cells in villous epithelium.⁵⁵ A substantial number of T cells, including CD4 T cells, are found in the subepithelial region. Beneath this epithelium overlying individual follicles is a region called the dome, which contains large numbers of T cells, macrophages and dendritic cells, as well as some B cells. Antigen, which is pinocytosed by M cells, is transported to the dome region, where antigen presentation to T cells occurs. High levels of MHC class II antigens are expressed by macrophages and dendritic cells. Follicles lying beneath the dome contain mantle zones with predominantly resting B cells, most of which express IgM and IgD on their surface. Virtually all Peyer's patch follicles also have germinal centers that contain activated B cells, follicular dendritic cells (FDC), CD4 T cells, and tingible-body macrophages (so called because of their appearance after they have phagocytosed cellular debris). Many of the B cells within Peyer's patch germinal centers express surface IgA, and it is believed that this is where IgA class switch occurs. Very few CD8 T cells are located within the follicles. An interfollicular region contains

Fig. 2.9 Germinal center in terminal ileum.

predominantly CD4 and CD8 T cells, as well as dendritic cells, macrophages, and some B cells. CD4 T cells predominate over CD8 T cells in this region as well as in the dome.

The diffuse tissue of the gastrointestinal tract consists of two components: the lamina propria and intraepithelial lymphocytes (IEL). The lamina propria is located immediately beneath the epithelium. A key effector function of the lamina propria is the secretion of antibodies, primarily IgA. IgA is the major isotype produced by plasma cells in lamina propria regions; however, IgM represents 10–18% and IgG 3–5% of all Ig produced. Two IgA subclasses occur, IgA₁ and IgA₂, and the former represents >90% of IgA in the respiratory tract and >60% in the lamina propria of the small intestine.⁵⁶ Interestingly, IgA₂ increases in the lower ileum and becomes the predominant IgA subclass in the colon and rectum. IgA is transported from

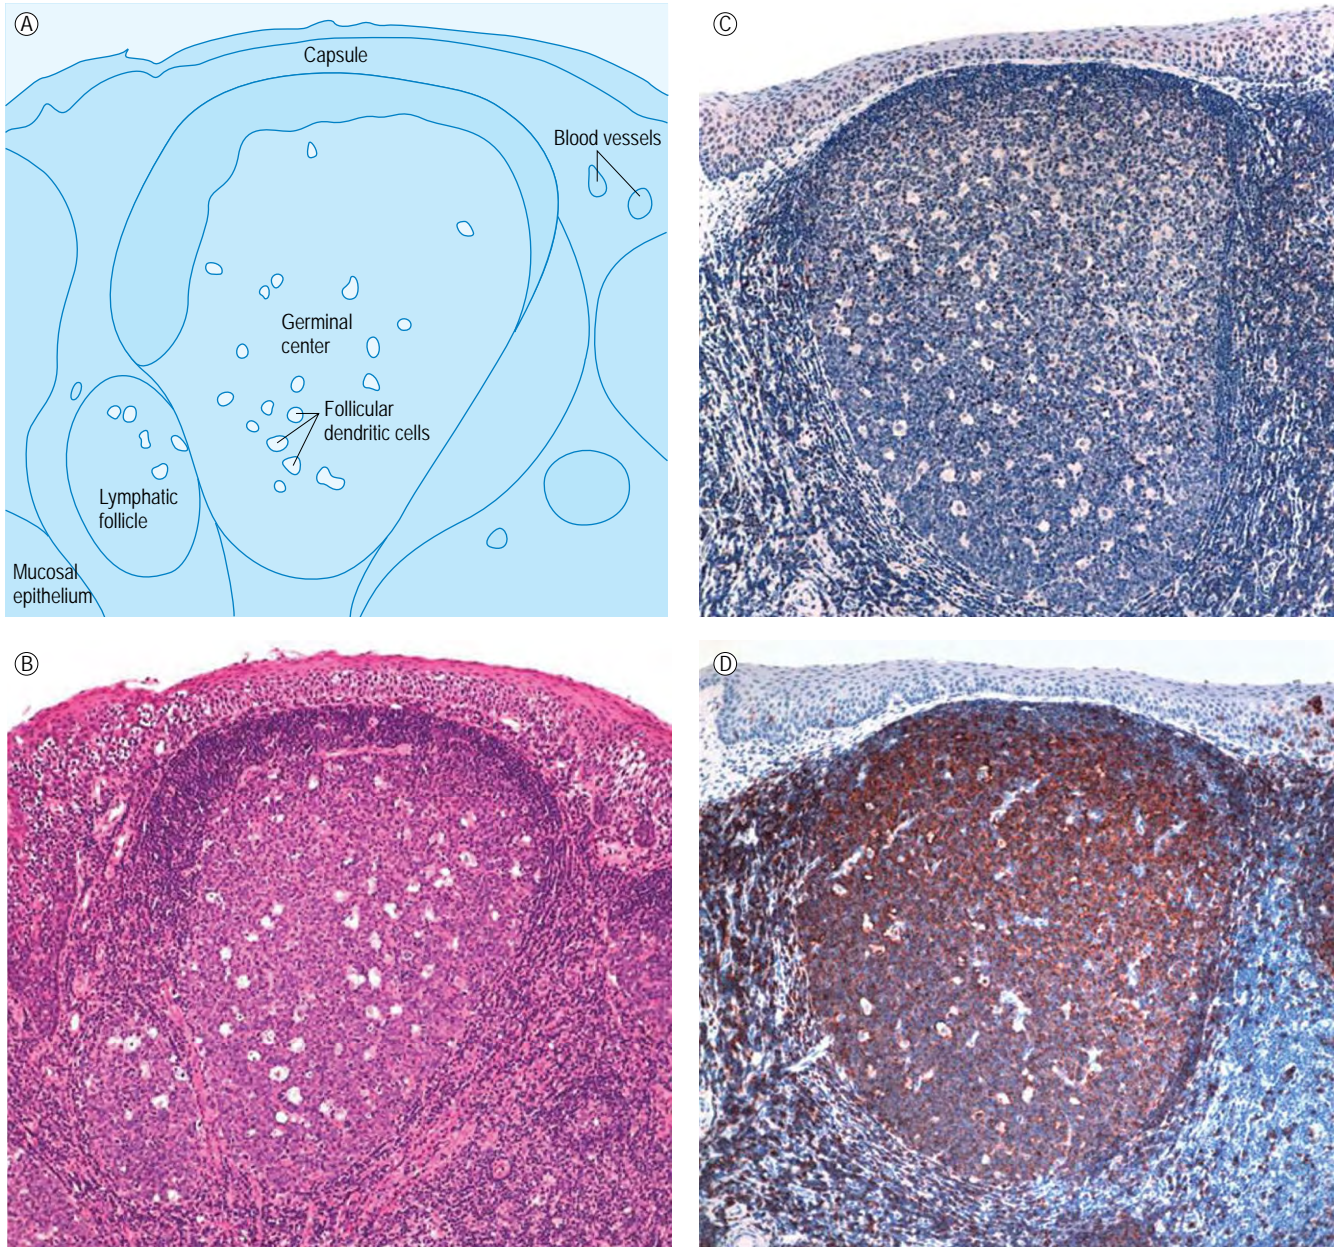

Fig. 2.10 Human tonsil. **(A)** Organization of lymphoid follicles and germinal centers. **(B)** Tonsillar tissue stained with hematoxylin and eosin. **(C)** Tonsillar tissue stained with anti-CD3 to demonstrate the distribution of T cells. **(D)** Tonsillar tissue stained with anti-CD19 to demonstrate the distribution of B cells.

the lamina propria into epithelial cells through polymeric immunoglobulin receptor-mediated uptake and subsequently secreted into the lumen. The lamina propria also contains large numbers of CD4 and CD8 T lymphocytes, CD4 T cells being about twice as prevalent as CD8 T cells. Almost all lamina propria T cells (>95%) express $\alpha\beta$ TCR. In addition, the lamina propria contains some B lymphocytes, the majority of which express IgM. Normally, very few IgG B cells are present in the lamina propria, although in certain inflammatory conditions, such as inflammatory bowel disease, the number of IgG-producing B cells and plasma cells increases dramatically. Other cells, including macrophages, dendritic cells, eosinophils, mast cells, and a few neutrophils, are also found in the lamina propria and play a role in mediating the effector functions of this tissue. The gastrointestinal tract contains the largest number of resident macrophages in the body. These express CD68, lysozyme, ferritin, MHC II, and CD74.

Intraepithelial lymphocytes (IEL) are found at the basal surface of the epithelium as well as interdigitated with epithelial cells. The vast majority of IEL (>90%) are T cells, which are either CD8⁺ or CD4-CD8⁻.⁵⁷ Although the majority of the IEL T cells express the $\alpha\beta$ TCR, a substantial number express the $\gamma\delta$ TCR. The function of IEL remains incompletely understood, but they generate cytotoxic activity as well reducing oral tolerance. As part of their effector function they produce several cytokines, including IL-5 and IFN γ . Finally, epithelial cells in the small intestine express MHC class II antigens and consequently may play an important role in presenting antigen to T cells.

MUCOSAL IMMUNE SYSTEM: RESPIRATORY TRACT

Surrounding the entrance to the throat are the three tonsillar groups: palatine tonsil, lingual tonsil, and pharyngeal tonsil or adenoids.⁵⁸ They form a ring of lymphoid tissue surrounding the pharynx termed Waldeyer's ring. The tonsils reach full development in childhood and begin to involute by the time of puberty. In adults, the tonsils are usually atrophic. The palatine tonsils, one located on each side, lie at the entrance to the pharynx, each measuring approximately 2.5×1.25 cm. They are surrounded by a poorly organized capsule except at the pharyngeal surface, which is covered with stratified squamous epithelium. Trabeculae subdivide the tonsil into lobules. Blood vessels and nerves enter through the capsule and extend within trabeculae (Fig. 2.10). The surface of the tonsil is covered by pits, which are the openings of crypts. The crypts extend down into the tissue of the tonsil with branching, increasing the surface area exposed to contents of the pharynx. There are abundant lymphoid follicles in each lobule that contain germinal centers which are predominantly B cells. By contrast, the lymphoid tissue surrounding the follicles contains T cells, macrophages, dendritic cells, and some B cells (Fig. 2.10). The lingual tonsils consist of 35–100 separate crypts surrounded by lymphoid tissue and are located at the root of the tongue. The pharyngeal tonsils or adenoids are accumulations of lymphoid tissue, 2.5–4.0 cm long, located on the median dorsal wall of the nasopharynx. They contain a series of longitudinal folds but do not contain actual crypts. The lingual and pharyngeal tonsils also contain lymphoid nodules with germinal centers.

Inductive immune responses to inhaled antigens within the respiratory tract occur mainly in the bronchus-associated lymphoid tissue (BALT). BALT consists of lymphoid aggregates located within the bronchial wall near the bifurcations of the major bronchial branches (Fig. 2.11). These structures are analogous to the GALT present in the

Fig. 2.11 Lymphoid regions in the human lung.

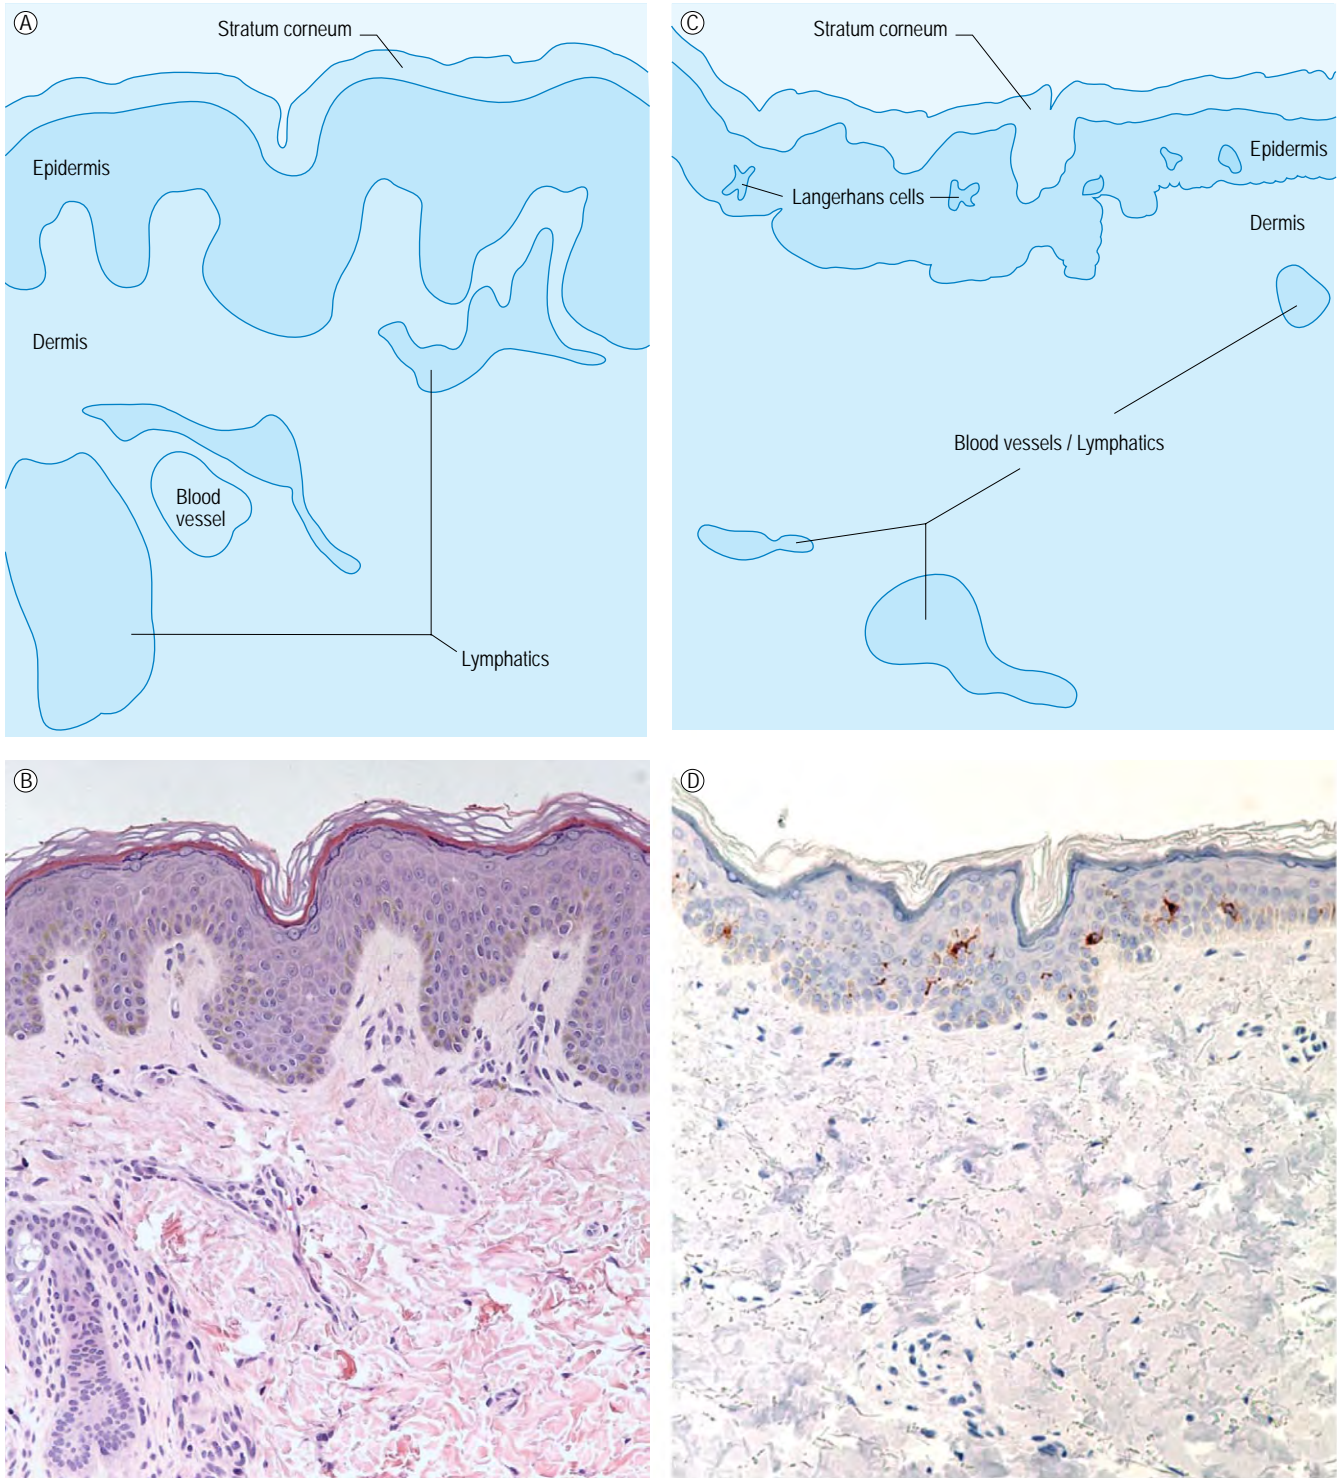

Fig. 2.12 Lymphoid regions in human skin. (A) Organization of the epithelial tissue. (B) Epithelial tissue stained with hematoxylin and eosin. (C) Epithelial tissue stained with anti-CD207 to demonstrate the distribution of Langerhans' cells (note brown cells).

gastrointestinal tract and function to provide a defense against inhaled microbes by induction of T- and B-cell responses. BALT development in humans is present at birth, and rapidly expands when exposed to antigenic stimulation. The specialized epithelium overlying the lymphoid aggregates consists of M cells heavily infiltrated with lymphocytes and significant dendritic cell populations present directly below the epithelium. As in the gastrointestinal tract, the main result of induction of immune responses in BALT is the production of secretory IgA.⁵⁹

Although quite extensive in the gastrointestinal tract, the diffuse mucosal tissue of the respiratory tract is minimal. Pools of lymphocytes are present within the lung interstitium, made up of 10–20% T cells. Macrophages play a significant role in the immune response in the respiratory tract and are present on both the air side of the lung and airways as well as in the mucosa.⁶⁰ Minimal inflammation occurs in the bronchial mucosa owing to the presence of regulatory T cells that inhibit T-cell activation and expansion. Instead, antigen is carried by local macrophages to the regional lymph nodes, which are the site of most of the respiratory effector immune responses.⁶¹ Communication occurs between the gastrointestinal and respiratory mucosae through cell trafficking. Antigen-reactive T and B cells from the Peyer's patches can populate the bronchial mucosa. This common mucosal immune system feature has been exploited to develop oral vaccines against respiratory microbes.⁶²

MUCOSAL IMMUNE SYSTEM: GENITAL TRACT

The male and female reproductive tracts are also components of the common mucosal system. However, the immune system in the genital tract is unique because it must maintain a delicate balance between tolerance of germinal center cells, spermatozoa, and fetus and the recognition of microbes. Most of what is known about the mucosal response in the genital tract has been learned from the female reproductive tract. Unlike the gastrointestinal and respiratory tracts, there is a minimal amount of induction of mucosal immune responses in the genital tract.⁶³ Much of the population of the mucosa results from induction of immune responses at other sites, predominately in the rectum and Peyer's patches, followed by homing of IgA cell precursors to the genital tract. Although secretory IgA is the predominant antibody found in the genital tract, monomeric IgA, IgM, and IgG are also present. The production and transport of antibody produced in the genital tract is thought to depend on both hormonal and local factors, including IL-1b, IL-6, and IL-10, which all influence the maturation of B cells to plasma cells within the mucosa.^{64, 65}

SKIN

The skin consists of two layers, the epidermis and the dermis. The epidermis is the outermost layer and contains three distinct cell types: keratinocytes, melanocytes, and Langerhans' cells (Fig. 2.12). Keratinocytes are squamous epithelial cells and are the principal cell type of the epidermis. Recent studies have shown that keratinocytes secrete a variety of cytokines, including IL-1, IL-6, IL-10, TGF- β , and TNF- α , that can profoundly influence immune responses. Thus, they probably play a significant role in regulation and/or modulation of immune responses in the skin. The second cellular constituent of the skin is the pigment-producing melanocyte. This cell is derived from the

neural crest and resides in the basal layer of the epidermis. The third cellular component of the epidermis, and the one of particular importance for the immune system, is the Langerhans' cell. Langerhans' cells are found scattered throughout the epidermis within the malpighian layer, or prickle cell layer. These cells play a role in the induction of T-cell responses, which can give rise to contact dermatitis, graft rejection, and other immune responses, both normal and pathologic. When these cells encounter antigen, in concert with exposure to cytokines provided by keratinocytes such as TNF- α , they migrate from the epidermis to the dermis, then enter the afferent lymphatics and migrate to draining lymph nodes. There they participate in the generation of a primary immune response, presenting antigen to T cells.⁶⁶

Under the epidermis is the dermis, which contains abundant fibroblasts producing collagen, a principal component of skin. The dermis also contains blood vessels and various epidermal adnexal structures, such as hair follicles, sweat glands, and sebaceous glands. The vasculature of the dermis consists of an extensive network of plexuses containing arterioles, capillaries, and venules. Dermal lymphatics are found in association with the vascular plexuses. In normal skin, a small number of lymphocytes can be found in perivascular areas. These lymphocytes are mostly T cells that have certain unique features, including expression of a memory phenotype (CD45RO⁺) and expression of a cutaneous lymphocyte-associated antigen that binds to the vascular addressing endothelial cell leukocyte adhesion molecule-1 (ELAM-1) (CD62E) present on the endothelium. This latter interaction appears to play an important role in the homing of memory T cells to inflamed regions of the skin. The dermis also contains mast cells that play an important role in immediate hypersensitivity reactions in the skin.

ACKNOWLEDGMENTS

We would like to thank Dr Edwina Popek, Pathology Department, Texas Children's Hospital, Houston, Texas, for providing histopathological images of lymphoid tissues; Dr Gregory Stelzer and Wendy Schober for the flow cytometric display; Eleanor Chapman, Anna Wirt, Terry Saulsberry and Yvette Wyckoff for typing the manuscript; and Dr Jerry McGhee for critical review of the first edition.

Innate immunity

Ken J. Ishii, Shizuo Akira

3

All living organisms are continuously exposed to foreign entities including food, microorganisms, and unnecessary self metabolites. As a result, there is a continuing need to discriminate dangerous nonself from safe self, particularly when life-threatening microorganisms invade the body. Jawed vertebrates have evolved two arms of immune defenses against invading pathogens: innate (natural) and adaptive (acquired) immunity (Fig. 3.1). Innate immunity is the first line of host defense. It includes the physical barrier of skin and the mucosal layer, and inflammatory responses by 'innate' immune cells such as granulocytes and macrophages that can be triggered in minutes and are then followed by activation of dendritic cells and natural killer (NK) cells. Adaptive (acquired) immune responses are slower processes that are mediated by T cells and B cells, whose highly diverse antigen receptors are generated by complex DNA rearrangement events and thus have the potential to recognize novel antigens as well as conserved ones (Chapter 4).

In contrast to adaptive immunity, innate immunity had long been regarded as a relatively nonspecific system, with its main roles being to engulf and destroy pathogens, to trigger proinflammatory responses, and to help present antigen, thereby priming adaptive immune responses. However, recent studies have shown that the innate immune system has a great degree of specificity that enables it to discriminate efficiently between self and foreign entities, including microorganisms and unnecessary self molecules. This discrimination relies, to a great extent, on pattern recognition receptors (PRRs), which include the Toll-like receptors (TLRs), NOD-like receptors (NLRs), and the recently described RIG-I-like receptors (RLRs). All of these receptors can play a crucial role in early host defense against invading pathogens (Table 3.1 and Fig. 3.2). Unlike the T-cell and B-cell antigen receptors, these PRRs are entirely germline-encoded and are expressed constitutively by both immune and nonimmune cells. They recognize conserved microbial components known as pathogen-associated molecular patterns or PAMPs.¹ Following PAMP recognition, PRR activate specific signaling pathways that lead to robust but highly defined innate immune responses. These innate responses then help prime subsequent protective adaptive (antigen-specific) immune responses to the inciting pathogens.

In addition to their 'primary function' of fighting invading microbes, PRR are also involved in the pathogenesis of many diseases. In particular,

PRR recognition of self-molecules derived from the host (e.g., nucleic acids) may be linked to autoimmune diseases and possibly to other immunological disorders. In humans, PRRs and their mutations (e.g., single nucleotide polymorphisms (SNPs)) have recently been linked to susceptibility, not only to infectious diseases, but also to chronic inflammatory diseases, such as atherosclerosis and asthma² (Chapter 40).

This potential involvement of innate immune system in a variety of human diseases has attracted the interest of a wide range of clinical fields.³ Agonists and antagonists for TLRs, NLR and RLR, as well as inhibitors of their signaling molecules, are presently under development for a variety of therapeutic applications. Choosing highly 'effective and proper' but 'safer' PRR-agonists/antagonists is critical for the development of improved vaccine adjuvant and immunostimulatory agents. PRR antagonists or inhibitors of PRR-signaling molecules, on the other hand, may provide another opportunity for the development of drugs to prevent and/or treat diseases in which PRRs are involved in the etiology or pathogenesis. In this chapter, we discuss recent advances and understanding of the innate immunity-related research field, including the molecular and cellular mechanisms underlying PRR-mediated innate immune responses and their impact on human diseases.

KEY CONCEPTS

THE INNATE IMMUNE SYSTEM

- >> The innate immune system is the first line of host defense against pathogens
- >> It helps prime subsequent activation of the adaptive immune system
- >> Unlike the antigen receptors of the adaptive immune system, its pattern recognition receptors (PRRs) are entirely germline-encoded
- >> PRRs recognize conserved microbial components known as pathogen-associated molecular patterns or PAMPs

KEY CONCEPTS

THE MAJOR PATTERN RECOGNITION RECEPTORS OF THE INNATE IMMUNE SYSTEM

Toll-like receptors (TLRs)

- >> Reside on the cell surface or phago/endosome membranes
- >> Include 11 different type I integral membrane glycoproteins in the multigene family
- >> Contain a ligand-sensing leucine-rich repeat (LRR) extracellular domain and a Toll/IL-1R homology (TIR) cytoplasmic signaling domain

Nod-like receptors (NLRs)

- >> Reside in the cytoplasm
- >> Include 22 different family members, most of whom remain to be fully characterized
- >> Contain a ligand-sensing LRR and a domain for the initiation of signaling such as CARDs, PYRIN, or baculovirus inhibitor of apoptosis repeat (BIR) domains

RIG-I-like receptors (RLRs)

- >> Reside in the cytoplasm
- >> Include three different family members
- >> Contain a C-terminal DExD/H box RNA helicase that can recognize RNA, with or without an N-terminal CARDs signaling domain

INNATE IMMUNE SENSORS AND THEIR FUNCTIONS

TOLL-LIKE RECEPTORS

An important role of the innate immune system in the first-line defense against pathogens and the underlying molecular and cellular mechanism(s) has recently been unveiled. The Toll pathway in *Drosophila melanogaster* was initially discovered as a receptor essential for embryonic patterning. The identification of the Toll pathway as a critical component of the host defense against fungal and Gram-positive bacterial infections in insects in 1996⁴ provided the impetus for the subsequent identification of mammalian homologues, the evolutionarily conserved TLRs.¹ These mammalian TLRs form a class of PRR molecules that currently consists of 11 members that can recognize microbial components known as PAMPs.^{5, 6} The TLRs are type I integral membrane glycoproteins characterized by extracellular domains that contain varying numbers of leucine-rich repeat (LRR) motifs and a cytoplasmic signaling domain homologous to that of the interleukin-1 receptor (IL-1R), termed the Toll/IL-1R (TIR) homology domain (Fig. 3.2).

Similar to the other PRRs, mammalian TLRs are widely distributed on/in the cells of the immune system. They are capable of discriminating among a variety of invading pathogens, including protozoa, fungi, bacteria, and viruses (Table 3.1). TLRs can be classified into subfamilies based on their genetic tree. The TLR1, TLR2, and TLR6 subfamily recognizes lipoproteins, whereas TLR3 and the highly related TLR7, TLR8, and TLR9 subfamily recognize nucleic acids. TLR4 recognizes lipopolysaccharide (LPS) and TLR5 is the receptor for bacterial flagellin. TLR11 recognizes a profilin-like molecule in *Toxoplasma gondii* (Table 3.1).

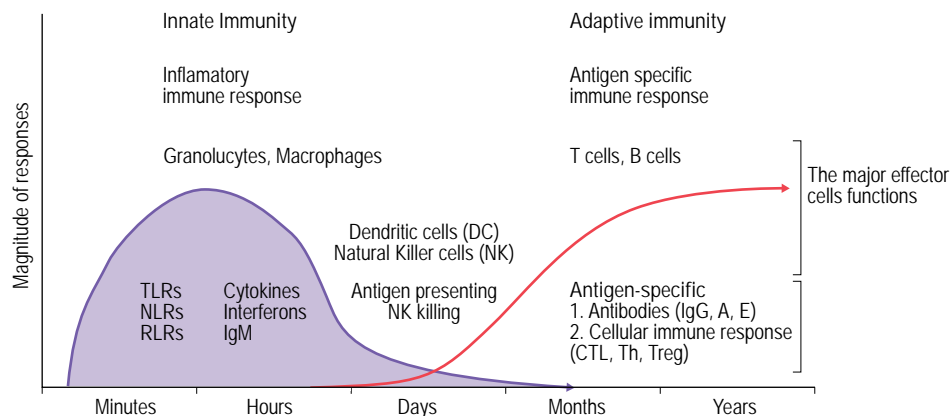

Fig. 3.1 Innate and adaptive immune responses to infection or tissue damage. When infection or tissue damage occurs, activation of innate immunity takes place within minutes and lasts for several days. Its purpose is to recognize and clear most of the microbes or damaged tissue. The adaptive immune response follows and peaks within the following weeks, resulting in an immunological memory that can last for the life of the individual.

Table 3.1 Mammalian pattern recognition receptors (PRRs)

Location	Pattern recognition receptors	Natural ligand	Species
Transmembrane	Toll-like receptors (TLRs)	TLR1 + TLR2	Bacteria
		TLR2	Fungi
		TLR3	Viruses
		TLR4	Gram-negative bacteria
		TLR5	Bacteria
		TLR6 + TLR2	<i>Mycoplasma</i>
		ssRNA	Virus, host
		TLR8	Virus, host
		TLR9	Bacteria, virus, plasmodium

CXCL16, transmembrane CXC chemokine 16; DC-SIGN, DC-specific ICAM-3 grabbing nonintegrin; dsRNA, double-stranded RNA; LPS, lipopolysaccharide; SR-A, scavenger receptor-A; ssRNA, single-stranded RNA.

TLR-ligand recognition can be flexible, permitting the recognition of a diverse range of molecules. For example, although TLR4 is associated with recognition of LPS, it also recognizes the fusion protein of respiratory syncytial virus (RSV), fibronectin, and heat-shock proteins. Similarly, TLR9 recognizes hemozoin, the heme-polymeric metabolite of the malaria parasite, as well as nucleic acids.

Localization of the various subfamilies in the cell varies. While certain TLRs (TLRs 1, 2, 4, 5, and 6) are expressed on the cell surface, others (TLRs 3, 7, 8, and 9) are found almost exclusively in intracellular compartments such as the endoplasmic reticulum and endosomes (Fig. 3.2). The physiological significance of these expression patterns remains unclear, but it is the common perception that ligands easily liberated from the pathogens such as flagellin and LPS are recognized by cell surface TLRs, while ligands hidden inside the pathogens such as nucleic acids are recognized in the endosome after lysosomal degradation of microbes or cells.

TLRs are expressed on various immune cells, including macrophages, dendritic cells, B cells, granulocytes, NK cells, and T cells, as well as on nonimmune cells such as fibroblasts and epithelial cells (Fig. 3.3). TLR expression can be altered in response to pathogens, a variety of cytokines, and environmental stresses. Taken together, the ability of single TLRs to detect a unique but diverse range of ligands and their ubiquitous expression and distinct localization within and between cells may enable the

KEY CONCEPTS

TOLL-LIKE RECEPTOR (TLR) SIGNALING

- >> The C-terminal Toll/IL-1R (TIR) domain can initiate differential intracellular signaling
- >> Except for TLR3, most TLRs, including TLR4, signal through an adapter molecule termed myeloid differentiation primary response gene 88 (MyD88)
- >> TLR3 signals through an adaptor molecule termed Toll/IL-1R domain-containing adaptor-inducing interferon- β (TRIF)
- >> TLR4 can also signal through TRIF
- >> Both MyD88 and TRIF can associate with tumor necrosis factor receptor-associated factor 6 (TRAF6), which leads to the activation of nuclear factor (NF)- κ B and/or the mitogen-activated protein kinase (MAPK) pathway

Fig. 3.2 Intracellular localization and signaling of Toll-like receptors (TLRs), NOD-like receptors (NLRs), and RIG-I-like receptors (RLRs). These pathogen recognition receptors are able to activate cells to produce proinflammatory cytokines and type I interferons. TLRs localize at the plasma membrane, such as the cell surface, and at endosomal membrane (as indicated). NLRs and RLRs are localized in the cytoplasm. Their cognate ligand (shown in Table 3.1) activates each pattern recognition receptor via distinct adaptor molecules. TLRs utilize either MyD88 and/or TRIF via their Toll/IL-1R homology (TIR) domain. RLR utilize interferon- β promoter stimulator 1 (IPS-1) via their CARD domain. NLRs activate caspase-1, leading to cleavage of pro-interleukin (IL)-1 or pro-IL-18 into the active forms.

host to sense invasion of a variety of pathogens even though the numbers of TLR genes are limited.

Direct interaction of a TLR with its cognate ligand triggers intracellular signaling pathways by means of multiple adaptors, including transduction and transcription molecules. This leads to robust immune responses that are characterized by the production of immunoglobulins, chemokines, and inflammatory cytokines with upregulation of co-stimulatory molecules (see next section), all of which are hallmarks of innate immune responses. The activation of dendritic cells via TLRs, in particular, is critically important owing to their ability to prime adaptive immune responses, thereby linking innate immunity to adaptive immune responses.

TOLL-LIKE RECEPTOR SIGNALING

Another important key to understanding TLR-mediated immune responses is the ability of the TIR domain to initiate differential intracellular signaling downstream of the TLR, with one signaling pathway that is shared with a member of the IL-1R superfamily.⁷ Myeloid differentiation primary response gene 88 (MyD88) is an essential adaptor molecule for most TLRs. The exception is TLR3 (Fig. 3.2). The other adaptor molecule, Toll-IL-1R domain-containing adaptor protein (TIRAP), acts specifically as part of the MyD88-dependent TLR2 and 4 signaling process. TLR3 and 4-mediated activation signals through Toll/IL-1R domain-containing adaptor-inducing interferon- β (TRIF), the so-called MyD88-independent pathway, lead

to the induction of IFN- β and IFN-inducible genes. The TRIF-related adaptor molecule (TRAM) characterizes the TLR4MyD88-independent, TRIF-dependent signaling pathway, and acts as a bridging adaptor between TLR4 and TRIF (Fig. 3.2).

Upon TLR stimulation, MyD88 and TRIF associate with tumor necrosis factor receptor-associated factor 6 (TRAF6), which leads to the activation of nuclear factor (NF)- κ B and/or the mitogen-activated protein kinase (MAPK) pathway. This leads to the production of several proinflammatory molecules, including cytokines and chemokines (reviewed in reference 7). TRAF6 forms a complex with ubiquitin-conjugating enzymes (Ub), such as Ubc13, and activates transforming growth factor- β -activated kinase 1 (TAK1). In turn, TAK1 activates transcription factors NF- κ B and activator protein-1 (AP-1) by means of the canonical I κ B kinase (IKK) complex and MAPK. The IKK complex is composed of two catalytic subunits, IKK α and IKK β . NEMO (NF- κ B essential modifier, also known as IKK γ) encodes the regulatory component of the IKK complex, which is responsible for activating the NF- κ B signaling pathway. IKK phosphorylates I κ B and targets it for degradation. The removal of I κ B enables NF- κ B to translocate into the nucleus, where it activates the transcription of various target genes.

In addition to these signaling pathways controlled by IKK complexes, TLR7/9-mediated MyD88-dependent signaling possesses a distinct signaling pathway for type I IFN production.⁸ MyD88 forms a complex with IL-1R-associated kinase 4 (IRAK4) and IRAK1. Depending on the types of cells or stimuli, TLR-MyD88-dependent signaling requires

Fig. 3.3 Toll-like receptor (TLR)-mediated innate and adaptive immune responses and their roles in the immune system. Both immune and nonimmune cells can express various TLRs. Cognate ligand(s), derived from either pathogens or damaged host cells, activate the cells and trigger intercellular signaling cascades. Activation leads to the production of humoral factors such as cytokines and chemokines, as well as cell–cell interactions. These orchestrate innate immune activations, especially those derived from certain dendritic cell (DC) subsets such as myeloid (conventional) DC (m(c)DC) and plasmacytoid DC (pDC), lead to the induction of antigen-specific adaptive immune responses. These responses are characterized by B-cell production of immunoglobulin (IgG), CD4 Th1 (or Th2) cell production of IFN γ , and CD8 T-cell-mediated cytotoxicity. Other types of immune cells that can be involved in this process are indicated. These TLR-mediated innate and adaptive immune responses can lead to protective immune responses to antigens of vaccines, allergens, or cancer antigens. They can also result in exaggerated innate and/or adaptive immune responses, which, in turn, may have detrimental effects, including the development of septic shock, atherosclerosis, or autoimmune diseases.

IRAK4 or IRAK1. While IRAK4 is necessary for most TLR-mediated proinflammatory cytokine production by macrophages and dendritic cells, IRAK1 is only essential for TLR7- and TLR9-mediated type I IFN production by plasmacytoid dendritic cells. TLR3 and TLR4 also mediate type I IFN production via another major adaptor molecule, TRIF, and the TRAF-family-member-associated NF- κ B activator (TANK)-binding kinase 1 (TBK1). TBK1 comprises a family with inducible I κ B kinase (IKK-i, also known as IKK-e). Together these kinases directly phosphorylate interferon regulatory factor 3 (IRF3) and IRF7. TBK1/IKK-i-mediated type I IFN induction is not restricted to TLR3 and 4, but is also involved in TLR-independent virus-, RNA- and DNA-induced type I IFN production.⁸

Transcription factors such as IRF5 and IRF7 are important mediators for TLR-dependent and -independent signaling pathways.⁹ In particular, IRF5 is involved in the production of most TLR-mediated proinflammatory cytokines, excluding IFN- α . This occurs independently of NF- κ B or the MAPK signaling pathway. In contrast, the IRF7 transcription factor plays a critical role in TLR7- and TLR9-mediated IFN- α production by both direct interaction with MyD88 and by TLR-independent type I IFN production that is induced by viruses.

TLR1, 2, 6, AND 10

TLR2 is a major mammalian TLR that can recognize lipoproteins derived from bacteria, viruses, fungi, and parasites. It acts by forming heterodimers with either TLR1 or TLR6.^{10–12} The molecular tree of the TLR family indicates that specific recognition of lipopeptide PAMPs involves TLR1, TLR2, TLR6, and TLR10.¹³ Thus, some structurally related TLRs can easily form heterodimers for the recognition of different ligands, as is the case for TLR2 together with TLR1 and TLR6. For example, *Mycoplasma* macrophage-activating lipopeptide 2 (MALP-2) is recognized by TLR2/TLR6 heterodimers, while the synthetic bacterial lipopeptide PAM₃CSK₄ is recognized by TLR2/TLR1 heterodimers. Altered ligand recognition has been attributed to the presence of a diacylated cysteine residue at the N-terminus of MALP-2. PAM₃CSK₄ contains a triacylated cysteine residue instead. Highly purified lipoteichoic acid from *Staphylococcus aureus* and *Streptococcus pneumoniae* was found to trigger innate immune responses through both TLR2/TLR6 and TLR2/TLR1 heterodimers. Similarly, glycerophosphatidylinositols with three fatty acids derived from *Plasmodium falciparum* are preferentially recognized by TLR2/TLR1 heterodimers,

whereas glycerophosphatidylinositols with two fatty acids are recognized with TLR2/TLR6 heterodimers.

Human TLR10 is an orphan member of the TLR family. It is present in a locus that also contains TLR1 and TLR6, and can also heterodimerize with TLR1 and TLR2.

TLR3

Double-stranded (ds) RNA is generated in host cells during the replication of most viruses. The host innate immune system thus recognizes dsRNA as a PAMP, inducing robust immune responses that are characterized by the production of type I IFNs and proinflammatory cytokines. While poly(I:C) synthetic dsRNA analogues are widely used as IFN inducers in many research and clinical applications, specific receptor-like molecules that recognize poly(I:C) have not been fully characterized.

It has been shown that TLR3 can confer strong dsRNA-induced NF- κ B activation in 293 cells when ectopically expressed and that TLR3 $^{-/-}$ mice display reduced responses to dsRNA, including poly(I:C).¹⁴ Accordingly, TLR3-deficient mice are susceptible to murine cytomegalovirus (MCMV) infection owing to reduced interferon production.¹⁵ In contrast, TLR3-deficient mice survive otherwise lethal West Nile virus infection owing to reduced virus entry into the brain and fewer TLR3-induced inflammatory responses, which contribute to pathogenesis rather than to protection.¹⁶

Poly-I:C was one of the first therapeutic agents used to treat human immunodeficiency virus (HIV) and leukemia patients, but was abandoned due to its toxicity.¹⁷ Several studies have been undertaken to reduce the toxicity of poly-I:C, with ongoing clinical trials against breast cancer and ovarian cancer. The dsRNA-induced, TLR3-mediated maturation of CD8 dendritic cells was shown to play an important role in the induction of antigen-specific CD4 and CD8 T-cell responses via type I interferon-mediated cross-priming.¹⁸ Yet dsRNA still stimulates dendritic cells from TLR3 $^{-/-}$ mice, especially when administered directly into the cytosol by transfection. This observation led to the discovery of an intracellular detection system that is independent of TLR3. This detection system is described in a later section.

TLR4

LPS is a major causative agent of sepsis. It triggers strong proinflammatory responses. The endotoxin shock that results is associated with high mortality. Although CD14 and LPS-binding protein were known to bind LPS, a sole receptor that recognize LPS to initiate proinflammatory response had been sought for decades before human Toll, homologous to fly Toll, was found. Most strikingly, it was shown that mice lacking TLR4 function were hyporesponsive to LPS.^{19–21} Thus TLR4 proved to be the “long-sought” receptor for LPS. The other TLRs were also found to recognize specific microbial products, many of which are also known to cause a robust inflammatory response.

TLR4 recognizes LPS via a homodimeric form that cooperates with MD2. Unlike the other TLRs, TLR4 utilizes as many as four adaptor molecules, as described above, which creates complex signaling pathways.⁷

In a mouse model, TLR4-deficient mice were found to be resistant to experimental septic shock induced by LPS. A similar phenomenon was observed in humans, in that some people with the TLR4 polymorphisms Asp299Gly and Thr399Ile were hyporesponsive to inhaled LPS. Further studies sought to link these SNPs and susceptibility to several infections,

including RSV infection, brucellosis, severe malaria, and candidal bloodstream infections. TLR4 and several other TLR polymorphisms were then found to be related to chronic inflammatory diseases, such as *inflammatory bowel disease* (Chapter 74) and *sarcoidosis* (Chapter 72). Thus TLR4 plays an important role in both protective immune responses to various infectious diseases and in pathological responses that occur in chronic inflammatory diseases.

Despite the pathogenic roles described above, due to their potency in eliciting innate immune responses, LPS and its purified products have been used as pharmaceutical agents. Initially, purified LPS (which contains lipid A) was thought to provide prophylactic protection against subsequent bacterial or viral challenge in animals; however, its extreme toxicity prevented extensive use. Efforts to eliminate the toxicity of lipid A led to the development of monophosphoryl lipid A (MLA or MPL).²² MLA has been shown to be safe and effective in human clinical studies as a new-generation vaccine adjuvant against infectious diseases and seasonal allergic rhinitis. Lipid A analogs have been demonstrated to act as LPS antagonists by blocking the effects of endotoxin. They have been used in clinical trials against sepsis and the complications of coronary artery bypass surgery. Thus, TLR4 ligands are apparently a double-edged sword, requiring attention to address safety concerns in order to make use of their potency for therapeutic applications.

TLR5

TLR5 recognizes flagellin, a protein that is found in the flagellar structure of many bacteria.²³ TLR5 is expressed in epithelial cells in the lung and gut, as well as residual dendritic cells, such as those located in the lamina propria of the intestine.²⁴ TLR5 may act as both an immune sensor and as a receptor to capture flagellated bacteria. Flagellin is a potent immune activator, stimulating diverse biologic effects that mediate both innate inflammatory responses and the development of adaptive immunity. Signaling of flagellin via TLR5 enhances the diversity of the response by engaging the MyD88-dependent pathway to activate the proinflammatory responses. Due mainly to its ease of manipulation, the protein nature of flagellin is considered an advantage for many immunotherapeutic applications, for example as a vaccine adjuvant.

TLR7 AND TLR8

Single-stranded RNA genome oligonucleotides derived from HIV or influenza virus, some ds short interference (si) RNAs developed for RNA interference (RNAi), and small synthetic compounds known as imidazoquinolins are recognized by TLR7 in mice and by TLR7 and TLR8 in humans. TLR7 and TLR8 subsequently activate various immune cells that elicit type I IFNs as well as cellular immune responses.^{25–27} The immunostimulatory effect of these RNAs is abrogated by various types of methylation. In humans, TLR7, but not TLR8, is highly expressed in plasmacytoid dendritic cell to produce type I IFNs, while TLR8, but not TLR7, is highly expressed in monocytes to produce proinflammatory cytokines, especially IL-12. TLR7 and possibly TLR8 utilize MyD88 as an essential adaptor for downstream signaling pathways. Owing to its ability to stimulate type I IFN production, several TLR7 agonists have been approved for clinical use in various viral infections. The TLR7 agonist imiquimod has been shown to be effective for external genital warts, basal cell carcinoma, and actinic keratosis and is in phase I clinical trials against human papillomavirus.³ Several other

synthetic TLR7 agonist compounds have been in phase I or phase II trials against hepatitis B virus, hepatitis C virus, and cancer.

Recent evidence suggests that TLR7 also recognizes autoantigens complexed with RNA, such as U1snRNP (nuclear self-antigen) in mice. Thus TLR7 may also play an important role in the pathogenesis of systemic lupus erythematosus (SLE), functioning as a double-edged sword similar to the other TLRs.

TLR9

TLR9 recognizes unmethylated CpG (cytosine phosphate guanosine) motifs found in bacterial and viral DNA.²⁸ Synthetic oligo deoxy nucleotides (ODNs) that contain these CpG motifs trigger TLR-mediated, MyD88-dependent signaling of macrophages, dendritic cells, and B cells to produce proinflammatory cytokines, chemokines, and immunoglobulins.²⁹ Some types of CpG DNA can activate plasmacytoid dendritic cells to produce a large amount of IFN- α . The robust innate immune response to CpG ODNs enables the host to be resistant to various intracellular infectious organisms. It skews the host's immune milieu in favor of Th1 cell responses and proinflammatory cytokine production.

CpG ODNs are being developed as immunoprotective agents, vaccine adjuvants, and anti-allergens.³⁰ Preclinical studies provide evidence that CpG ODNs are effective for each of these uses and can modulate the immune response to co-administered allergens and vaccines. CpG ODNs have had promising results in human use and have entered phase III clinical trials against several types of cancer, including melanoma, lymphoma, and nonsmall-cell lung cancer, either alone or in combination with chemotherapy.³¹ The other promising application of CpG ODN under clinical development is a vaccine composed of allergen antigen conjugated with CpG ODN to treat or prevent allergic diseases. CpG ODN skews the Th2 allergic immune milieu to a protective Th1 immune milieu, whereby allergic symptoms are diminished or reduced.

Recent evidence suggests that TLR9 can also recognize DNAs that do not contain CpG motifs. Moreover, TLR9 also recognizes molecules other than DNA, such as heme metabolites derived from malaria-infected red blood cells and self-DNA-chromatin complexes often observed in autoimmune diseases, including SLE. The physiological roles of TLR9 in the etiology and pathogenesis of malaria infection or autoimmune diseases such as SLE, however, are still unclear. As CpG ODN has become a promising compound for many immunotherapeutic applications including vaccine adjuvant, allergy, and cancer, the potential role of TLR9 in the pathogenesis of various diseases needs to be clarified in the future.

NOD-LIKE RECEPTORS AND THEIR FUNCTIONS

TLRs reside either on the cell surface or on phago/endosome membranes, suggesting that the TLR system is not optimal for the detection of pathogens that have invaded or escaped into the cytoplasm. Recent evidence suggests that such pathogens are detected by cytoplasmic PRRs, which can also activate the innate immune system.^{32,33}

A number of cytoplasmic PRRs have now been identified. Currently they are subclassified into NOD-like receptors and RIG-helicase-like receptors. These protein families are implicated in the recognition of bacterial and viral components, respectively, while both are also implicated in the intracellular recognition of endogenous components, including uric acids and nucleic acids that may become dangerous to host cells

(danger signal). Proteins in NOD families possess LRRs that mediate ligand sensing; a nucleotide-binding oligomerization domain (NOD) and a domain for the initiation of signaling, such as CARDs, PYRIN, or baculovirus inhibitor of apoptosis repeat (BIR) domains. Counting the IPAF, NAIP, and CIITA group of proteins, 22 NLR members have been identified to date. However, the biological significance of most of the NLRs remains to be determined (Table 3.1 and Fig. 3.2).

NOD1 AND NOD2

NOD1 and NOD2, initially identified and characterized as NLR, contain N-terminal CARD domains. NOD1 and NOD2 detect κ -D-glutamyl-meso-diaminopimelic acid (iE-DAP) and muramyl dipeptide (MDP), found in bacterial peptidoglycan, respectively. Although direct binding between NOD protein and their cognate ligands has not been demonstrated, consequent activation of NOD1 and NOD2 causes their oligomerization and the recruitment of RIP2/RICK, a serine/threonine kinase, to the NODs via their respective CARD domains. These homophilic interactions result in NF- κ B activation. In mice, macrophages lacking either NOD1 or NOD2 fail to produce cytokines in response to the corresponding ligand. In humans, a missense point mutation in the human *NOD2* gene is correlated with susceptibility to Crohn's disease.

THE NALP INFLAMMASOME AND OTHER NLRs

It has been shown that bacterial infections often induce activation of caspase-1, which catalyzes the processing of pro-IL-1 β to produce the mature cytokines. A complex of proteins responsible for these catalytic processes has been purified and designated the inflammasome.

The inflammasome consists of caspase-1; caspase-5; ASC (apoptosis-associated speck-like protein containing a CARD); and members of the NALP family, which are PYRIN-domain-containing proteins that also contain NOD-LRR. ASC is an adaptor protein that contains a PYRIN domain and a CARD. NALPs recruit ASC through a homotypic interaction between the PYRIN domains. In turn, ASC recruits caspase-1 via its CARD, leading to the activation of IL-1 β and IL-18 processing. Although the ligands for many members of the NALP family are currently unknown, NALP3 has recently been shown to recognize bacterial RNA (which is also known as TLR7/8 ligand), adenosine triphosphate (ATP), and uric-acid crystals. As these compounds are not unique to bacteria or other pathogens, it seems that not only PAMPs but also the presence of host danger signals (danger-associated molecular patterns, or DAMPs)³⁴ can be sensed by NALP3 in inflammasomes. Despite the existence of 14 NALP families, most of the known danger signals seem to activate caspase 1 through the NALP3 inflammasome, suggesting that NALP3 may represent one of the long-sought host danger receptors.

Interestingly, mutations in the NALP3 gene have been identified and found to be associated with three autoinflammatory disorders: Muckle-Wells syndrome, familial cold autoinflammatory syndrome, and neonatal-onset multisystemic inflammatory disease.³⁵ These disorders are associated with constitutive release of IL-1 β from monocytes of patients, suggesting that the mutations trigger spontaneous NALP3 oligomerization without the need for a ligand. Importantly, patients with NALP3 mutations are now being treated with the IL-1R antagonist, which has been shown to relieve all symptoms, including rashes, periodic fever, and arthritis.

Another NOD-LRR protein, NAIP5, is involved in caspase-1-dependent susceptibility of macrophages to *Legionella pneumophila*. It detects flagellin in cytoplasm. IPAF, another CARD-containing NOD-LRR protein, has been shown to recognize *Salmonella typhimurium*, which also results in caspase-1 activation. Interestingly, IPAF is also required for *L. pneumophila* growth restriction. Although the mechanism for how these two proteins intracellularly recognize the same ligand is not yet clear, NAIP5 and IPAF may cooperate for recognition of such bacterial components, since they can physically interact with each other. Importantly, *Legionella*-induced IL-1 β release, but not bacterial growth, is restricted in ASC-deficient macrophages. This suggests that NAIP has an antibacterial role that is independent of the NALP inflammasome.

RIG-LIKE RECEPTORS

Innate immune responses against invading viruses also rely on detection of viral PAMPs and subsequent production of antiviral cytokines such as type-I IFNs. dsRNA is one of the most frequently used viral PAMP. It does not normally exist in host cells but is generated intracellularly during viral replication. While dsRNA activates macrophages and dendritic cells via TLR3 to secrete proinflammatory cytokines and type I IFNs, most virus-infected cells such as fibroblasts produce type I IFNs in a TLR3-independent manner.

Recently, three homologous DExD/H box RNA helicases were identified as cytoplasmic sensors of viral infection by means of RNA detection. These helicases are designated RLRs. Two family members, retinoic acid-inducible gene I (RIG-I; also called DDX58) and melanoma differentiation-associated gene 5 (MDA5; also called Helicard), share two N-terminal CARDs followed by an RNA helicase domain.³⁶ RIG-I, but not MDA5, can mount antiviral responses against the positive-strand single-stranded (ss) RNA virus Japanese encephalitis virus, and against negative-strand ssRNA viruses such as Newcastle disease virus, vesicular stomatitis virus, Sendai virus, and influenza virus. MDA5 senses the presence of the positive-strand ssRNA picornavirus encephalomyocarditis virus.³⁷ The protein LGP2 shares homology with RIG-I in its helicase domain, but lacks a CARD. It has been suggested that LGP2 acts as a negative regulator of RIG-I/MDA-5 signaling (Table 3.1 and Fig. 3.2).

IPS-1 (interferon- β promoter stimulator 1, also named as MAVS, VISA, or CARDIF), serves as a critical signaling adaptor for RIG-I/MDA5. IPS-1 is composed of an N-terminal CARD domain that resembles that of MDA-5 or RIG-I.^{8,32,33} When expressed in cells, this protein has the ability to induce activation of the type I IFN promoter as well as NF- κ B. This protein is present in the outer mitochondrial membrane, suggesting that mitochondria might be important for IFN responses. Downstream of RIG-I-IPS-1, noncanonical IKKs, including TBK1 and IKK-I, are activated to phosphorylate IRF-3 and IRF-7. Thus signaling pathways triggered by TLR stimulation and RIG-I converge at the level of TBK1/IKK-i.

C-TYPE LECTINS

Among the other PRRs, the mannose receptor is among the best-characterized C type lectin. It binds mannosyl/fucosyl or GlcNAc-glycoconjugate ligands on many bacteria, fungi, and protozoan parasites to mediate subsequent inflammatory responses. This mannose receptor also functions to clear glycosylated endogenous ligands. Thus it can act

both to detect foreign pathogens and to help in the clearance of injurious self molecules.

Dectin-1, another C-type lectin, is the major receptor for β -1,3-glucans; ligand binding induces phagocytosis, and reactive oxygen species production in macrophages. Dectin-1 can cooperate with TLR2 to recognize ligands, thereby enhancing immune activation.

Other C-type-like receptors, including DC-SIGN, DEC-205, and BDCA-2, are known to be expressed in dendritic cells. These receptors play a role in intertissue trafficking, as well as endocytic antigen (ligand) uptake. Both help dendritic cells in their role as professional antigen-presenting cells.

THE SCAVENGER RECEPTORS

The scavenger receptors (SR) are another example of innate immune receptors that can act as a PRR with additional functions. SR-A contributes not only to the endocytosis of modified low-density lipoprotein, but also to resistance to Gram-positive bacterial infections. These dual functions of SR-A result on the one hand in resistance to septic shock induced by LPS *in vivo* and on the other to susceptibility to atherogenesis.

CD36, another type of scavenger receptor, is required for binding and internalization of apoptotic cells as well as for pathogens such as malaria-infected red blood cells. CD36 can detect diacylglycerides and is thus

KEY CONCEPTS

CLINICAL RELEVANCE

Toll-like receptors (TLRs) can play an essential role in the initiation of human diseases and represent potential targets for therapeutic intervention. Examples include:

- >> TLR ligands serve as components of common vaccine adjuvants
- >> TLR9 recognition of nucleic acids may help trigger systemic lupus erythematosus and rheumatoid arthritis
- >> TLR 1, 2, 4, and 5 are expressed in atherosclerotic plaques
- >> TLR agonists can skew the immune response from a Th2-allergic immune phenotype to a protective Th1 immune phenotype in asthma

By extension, TLR polymorphisms can either increase or decrease susceptibility to human diseases. Examples include:

- >> Increased susceptibility to Gram-negative bacterial septic shock, respiratory syncytial virus, malaria, *Brucella*, and *Candida* in polymorphisms of TLR4, which recognize lipopolysaccharide
- >> Increased susceptibility to *Legionella pneumophila* (legionnaire's disease), Crohn's disease, and ulcerative colitis in polymorphisms of TLR5, which recognize flagellin
- >> Decreased susceptibility to atherosclerosis in polymorphisms of TLR4
- >> Decreased susceptibility to systemic lupus erythematosus in polymorphisms of TLR5

Table 3.2 Single nucleotide polymorphisms (SNPs) of Toll-like receptors (TLRs) in human diseases

TLR	SNP(s) or genes	Effect on the disease
TLR2	Arg753Gln	Susceptibility to <i>Mycobacterium tuberculosis</i> or <i>Staphylococcus</i> infection. Increased risk for coronary restenosis. Resistance to Lyme disease. Associated with severe atopic dermatitis
	Arg677Trp	Susceptibility to leprosy Susceptibility to <i>M. tuberculosis</i>
	GT-repeat polymorphism in intron II -16934	Susceptibility to <i>M. tuberculosis</i> Reduced risk for asthma
TLR1, 2, 6	Nonsynonymous variants	Extension of inflammatory bowel diseases
TLR4	Asp299Gly and Thr399Ile	Hyporesponsiveness to LPS Susceptibility to meningococcal diseases in infancy Susceptibility to brucellosis Susceptibility to osteomyelitis by Gram-negative bacteria Hyporesponsive to <i>Porphyromonas gingivalis</i> Increased risk for bacterial vaginosis Association with Crohn's disease Risk factor for Crohn's disease Association with ulcerative colitis Lower incidence of carotid artery stenosis Lower incidence of acute coronary events Lower incidence of myocardial infarction Resistance to chronic obstructive pulmonary disease Associated with the severity of asthma Reduces the risk of developing late-onset Alzheimer's disease Associated with gastric MALT lymphoma
		Susceptibility to septic shock
		Susceptibility to severe RSV infection
		Resistance to legionnaire's disease
		Susceptibility to <i>Candida</i> bloodstream infections
		Association with chronic sarcoidosis
		Decreased susceptibility to rheumatoid arthritis
		Lower incidence of allograft rejection
		Susceptibility to severe malaria
		Association with ulcerative colitis
TLR5	392STOP	Increased risk of severe acute graft-versus-host disease
		Risk for ischemic stroke
		Increased risk of prostate cancer
		Lower risk of prostate cancer
TLR6	Ser249Pro	Susceptibility to meningococcal diseases
		Susceptibility to legionnaire's disease Association to Crohn's disease. Resistance to systemic lupus erythematosus
TLR9	T-1237C	Decreased risk for asthma Association with Crohn's disease Increased risk of pouchitis
TLR10	c.+1031G>A and c.+2322A>G	Association with asthma
	Haplotype GCGTGGC variant	Association with risk for nasopharyngeal carcinoma

MALT, mucosa-associated lymphoid tissues; RSV, respiratory syncytial virus.

nonredundant for most, but not all, TLR2/6-mediated innate immune activations. *Drosophila* RNAi screening has shown that a CD36 family member is required for mycobacterial infection, indicating its important role in innate immune recognition of diverse molecules, including pathogens and damaged host cells.

THE INNATE IMMUNE SYSTEM AND HUMAN DISEASE: PATHOGENESIS, PREVENTION, AND THERAPY

TOLL-LIKE RECEPTORS AND HUMAN DISEASE

A number of studies have now linked SNPs in TLRs and a variety of human diseases, including infectious diseases, asthma, atherosclerosis, and autoimmune diseases.³⁸ Identification and functional characterization of such polymorphisms in TLRs as well as the other PRRs have the potential to provide new insights to the role played by genetic susceptibility to these diseases, to improve understanding of the natural history of the disease, and to evaluate better diagnostic and therapeutic strategies. For example, knowing the TLR SNP genotype of patients suffering from severe infectious disease may allow clinicians to individualize treatment and better predict the outcome.

TLR agonists or antagonists provide new means to treat immune disorders. For example, TLR antagonists may be useful when TLR-mediated innate immune activation in response to either infection or tissue damage is likely to result in deleterious outcomes, such as sepsis, autoimmune disease, or atherosclerosis. Conversely, agonists might be beneficial in situations where inhibition of TLR signaling leads to innate and/or adaptive immune deficiency (immunological tolerance or impaired Th1 responses).

TOLL-LIKE RECEPTORS AND INFECTIOUS DISEASES

The development of antibiotic resistance and bacterial product-related complications such as septic shock are major concerns in the treatment of Gram-negative and Gram-positive infections. Elucidation of the role of the TLRs in innate immunity has provided a number of new insights to the pathophysiology of infection and new avenues for treatment. For example, TLR4 recognizes LPS, a major component of Gram-negative bacterial cell walls that causes septic shock. Two well-known TLR4 polymorphisms, Asp299Gly and Thr399Ile, have been found to be linked not only to susceptibility to Gram-negative bacterial septic shock but also to susceptibility to a variety of other microbial infections, including RSV, malaria, *Brucella*, and *Candida* (Table 3.2).

As a result of TLR ligand diversity, individual polymorphisms can lead to either susceptibility or increased resistance to different microbial agents. For example, TLR2 recognizes a variety of bacterial, viral, fungal, and parasite components, such as the lipoprotein found in bacterial cell walls. TLR2 deficiency induces susceptibility to *Borrelia burgdorferi* in mice, permitting high bacterial loads. And humans with the TLR2 Arg753Gly polymorphism demonstrate a reduced response to *Staphylococcus* infections. Conversely, individuals with the TLR2 Arg753Gly polymorphism appear to be resistant to *B. burgdorferi* Lyme disease. The TLR2 polymorphism, Arg677Trp, is similarly associated

with susceptibility to tuberculosis and leprosy, linking TLR2 genetic variants to human mycobacterial infections.

TLR5 is another case in point. TLR5 recognizes bacterial protein flagellin, which is found in the flagellar structure of many bacteria. Humans with a stop codon polymorphism in the ligand-binding domain of TLR5 (392STOP) have been shown to be highly susceptible to *Legionella pneumophila* (legionnaire's disease: Table 3.2). The same stop codon polymorphism protects people from developing SLE, parenthetically providing another potential link between infectious diseases and autoimmunity.

TLRs AND PRIMARY IMMUNODEFICIENCY

Primary immunodeficiency diseases of humans are caused by a variety of immunological defects. These deficiencies are typically marked by an increased susceptibility to infectious agents. Recent studies have suggested that TLR signaling can be abnormal in several of these syndromes.³⁹ For example, patients with *X-linked hypohydrotic ectodermal dysplasia with immunodeficiency (hyper-IgM syndrome)* (Chapter 34), who exhibit increased susceptibility to pyogenic and atypical mycobacterial infections, were found to have a mutation in the *IKBK* gene, which results in defective production of IKK γ (NEMO). NEMO encodes the regulatory component of the IKK complex, which is responsible for activating the NF- κ B signaling pathway. Similarly, autosomal dominant hypohydrotic ectodermal dysplasia with immunodeficiency results from defects in the phosphorylation and degradation of I κ B α , which also leads to abnormal activation of NF- κ B. Mice with IRAK4 deficiency, an essential signaling molecule for most TLR-mediated signaling and human patients with autosomal recessive amorphic mutations in IRAK4 both demonstrate susceptibility to bacterial infections.

TLRs, GASTROINTESTINAL DISORDERS, AND INFLAMMATORY DISEASES

TLRs also appear to play an important role in mucosal immunity. Both TLR4 and TLR2 are involved in the recognition of LPS and HSP60 derived from *Helicobacter pylori* in gastric mucosa. TLR2, TLR4, and TLR5 play critical roles in host defense against gastrointestinal infections with *Salmonella typhimurium*. TLR4 aids in the early detection of *S. typhimurium* infection. TLR5 recognizes *S. typhimurium* flagellin, but appears to play a limited role in host defense against *S. enterica*, which causes typhoid fever. These observations suggest that innate immune responses can play a crucial role during the invasive phases of bacterial infection.

Crohn's disease and *ulcerative colitis* (Chapter 74) are chronic inflammatory diseases of the bowel. Chronic mucosal inflammation appears to be the result of excessive secretion of proinflammatory cytokines in the gastrointestinal tract. TLRs appear to be involved in this process. Indeed, TLR4 has been implicated in the triggering of Crohn's disease in mice. TLR4 expression has been found to be elevated in both ulcerative colitis and Crohn's diseases and the common Asp299Gly and Thr399Ile polymorphisms of *TLR4* have been linked to the disease etiology. Strong antibody responses to flagellin of commensal bacteria have been observed in Crohn's disease but not in ulcerative colitis. The *TLR5* stop codon polymorphism has been found to be negatively associated with Crohn's disease, suggesting that immune responses to flagellin via TLR5 may

promote pathogenesis. Conversely, *TLR9* (T-1237C) polymorphisms have also been associated with Crohn's disease, but not ulcerative colitis.

Sarcoidosis is another inflammatory granulomatous multisystem disorder with an unknown etiology that pursues a chronic course in many patients. In a recent study, Asp299Gly and Thr399Ile polymorphisms of *TLR4* have been found to be associated with the chronic but not acute course of sarcoidosis, implicating TLRs in the etiology of the disease.

TOLL-LIKE RECEPTORS AND AUTOIMMUNITY

TLR-mediated innate immune activations are so potent that they may be deleterious to host in certain situations. In addition, TLR recognition of self molecules of the host (e.g., nucleic acids), which are not easily distinguishable from those of no-self (infectious organisms), has the potential to provoke autoimmune diseases and other immunological disorders. Indeed, TLR9 recognition of nucleic acids has been implicated in triggering *SLE* (Chapter 51) and *rheumatoid arthritis* (RA) (Chapter 52). Several mutations in *IRF5*, whose protein product plays an important role in the trans-activation of TLR9-mediated proinflammatory gene inductions, have been associated with an increased risk for SLE. Although it is still controversial whether TLRs are critically involved, innate immune responses seem to play an important role in the etiology and/or pathogenesis of this classic autoantibody-mediated disease.

Multiple sclerosis (MS) (Chapter 65) is an inflammatory demyelinating disease of the central nervous system with complex pathological features and disease courses. Recently, LPS recognition and *Chlamydia pneumoniae* infection have both been tentatively implicated in the pathogenesis of MS. Although TLR4 Asp299Gly and Thr399Ile mutations do not appear to influence the incidence of MS, in mice both TLR9 and MyD88 can act as essential modulators of the sterile autoimmune process during the effector phase of MS. This suggests that endogenous molecules, possibly nucleic acids, may play a role in the pathogenesis of MS. Conversely, pathological changes and disease severity of experimental inflammatory arthritis, including collagen-induced arthritis, can be reduced by guanine-rich ODN (suppressive ODN or inhibitory ODN), an antagonist of TLR9. This suggests that TLR9 may be involved in the pathogenesis of inflammatory arthritis and that TLR9 antagonists could potentially block or ameliorate the development of autoimmune diseases, such as MS or rheumatoid arthritis.

TOLL-LIKE RECEPTORS AND ATHEROSCLEROSIS

As multiple microorganisms, such as *C. pneumoniae*, *H. pylori*, and cytomegalovirus, have been shown to be involved in the inflammatory etiology of *atherosclerosis* TLR-mediated innate immune activations also appear to play a role in this disease. Most TLRs, particularly TLR1, 2, 4, and 5, are expressed in atherosclerotic plaques. Expression of these TLRs could potentially trigger the activation of NF- κ B and other transcription factors, resulting in upregulation of proinflammatory mediators.⁴⁰ In support of this hypothesis, it has been shown that MyD88 deficiency, with impaired TLR signaling, leads to delays in the onset of atherosclerosis.

One example of a TLR ligand is HSP60. This protein, which is expressed by *C. pneumoniae* that can be found in atherosclerotic lesions, can activate TLR4 and enhance the inflammatory process.

It is thus not surprising that people with the TLR4 Asp299Gly polymorphism have been found to have a reduced risk for coronary artery disease. In addition, the relatively common Arg753Gln polymorphism of TLR2 has been associated with coronary restenosis, further suggesting that certain pathogens containing ligand(s) for TLR2 or TLR4 (or other PRRs) could provide a link between inflammation and atherogenesis.

TOLL-LIKE RECEPTORS AND ASTHMA

The lung epithelium plays an important role in host defense against microbial colonization and infections. Numerous epidemiologic and experimental studies have suggested an inverse correlation between the incidence of infectious diseases and allergic/autoimmune disorders that may support the so-called hygiene hypothesis.⁴¹ In fact, microbial products or TLR ligands are being developed to treat or prevent allergic diseases. TLR agonists such as CpG DNA (TLR9 ligand) can skew the immune response from one exhibiting a Th2 allergic immune phenotype to a protective Th1 immune one. This shift can diminish or reduce allergic symptoms. However, there is also opposing evidence that an increased bacterial load or viral infections of the lung can lead to severe exacerbations of *chronic obstructive pulmonary disease* or *asthma*. Thus TLRs may serve as a double-edged sword. While certain polymorphisms of TLR6, TLR9, and TLR10 are associated with an increased risk of asthma, polymorphisms of TLR2 can reduce the risk.

TOLL-LIKE RECEPTORS AND VACCINES

Although TLRs have been discovered just recently, their ligands have been used as components of vaccine adjuvants for decades. More than 15 years ago, Charles A Janeway Jr. described these adjuvants as the 'immunologist's dirty little secret,' because they have been known to be critical components in vaccine formulation, needed in order to initiate adaptive (antigen-specific) immune responses to the vaccine antigen.⁴² For example, one of the most potent adjuvants, which is often used in animal models, is complete Freund's adjuvant (CFA). CFA contains mycobacterial products (possibly with TLR2, 4, or 9 ligands), whereas the less active incomplete Freund's adjuvant does not. Aluminum hydroxide gel (alum), the only clinically approved adjuvant, does not seem to contain any TLR ligand, and is quite weak in inducing cellular immune responses. On the other hand, CpG DNA, a ligand for TLR9, strongly activates dendritic cells, inducing them to produce IL-12 and type I IFNs. Expression of IL-12 and IFNs is followed by the development of strong Th1 immune responses, including antigen-specific IFN γ -producing Th1 cells and CTL. The efficacy of the TLR9 ligand as a vaccine adjuvant has been demonstrated in both primates and in humans. MPL, another well known adjuvant, contains lipid A, which is an immunostimulatory element of LPS. MPL and R848, a potent ligand for TLR7, are also being developed as vaccine adjuvants. Finally, TLR ligands have been shown to break immunological tolerance to tumor cells, and thus are under consideration for use as 'adjuvants' for antitumor vaccines.

SUMMARY

PRR-mediated innate immune recognition of a diverse range of molecules has attracted the interest of immunologists, researchers in other fields, and physicians. The physiological roles of PRRs in innate

and adaptive immune responses are still being uncovered, and the precise molecular and cellular mechanisms by which PRRs recognize the cognate ligand, influence intra- and intercellular signaling pathways and contribute to protective and/or pathological immune responses in both innate and adaptive immunity remain to be further clarified. The hope, however, is that research on innate immunity will have a direct impact on the future development of PRR agonists or antagonists as immunotherapeutic agents for infectious diseases, allergies, or cancer, as well as for immunological disorders, such as autoimmune diseases, atherosclerosis, or even diabetes.

Antigen receptor genes, gene products, and co-receptors

Raul M. Torres, John Imboden, Harry W. Schroeder Jr.

4

In 1890, von Behring and Kitasato reported the existence of an agent in the blood that could neutralize diphtheria toxin. The following year, glancing references were made to 'Antikörper' in studies describing the ability of the agent to discriminate between two immune substances, or bodies. The term antigen is a shortened form of 'Antisomatogen + Immunkörperbildner,' or the substance that induces the production of an antibody. Thus, an antibody and its antigen represent a classic tautology.

In 1939, Tiselius and Kabat used electrophoresis to separate immunized serum into albumin, α -globulin, β -globulin, and γ -globulin fractions. Absorption of the serum against the antigen depleted the γ -globulin fraction, yielding the terms gammaglobulin, immunoglobulin (Ig), and IgG. 'Sizing' columns were then used to separate immunoglobulins into those that were 'heavy' (IgM), 'regular' (IgA, IgE, IgD, IgG), and 'light' (light-chain dimers).

In 1949, Porter used papain to digest IgG molecules into two types of fragments, termed Fab and Fc. The constancy of the Fc fragment permitted its crystallization, and thus the elucidation of its sequence and structure. The variability of the Fab fragment precluded analysis until Bence Jones myeloma proteins were identified as clonal, isolated light chains.

In 1976, Hozumi and Tonegawa demonstrated that the variable portion of κ chains was the product of the rearrangement of a variable (V) and joining (J) gene segment. In 1982, Alt and Baltimore reported that terminal deoxynucleotidyl transferase (TdT) could be used to introduce a nongermline-encoded sequence between rearranging V, D for diversity, and J gene segments, potentially freeing the heavy-chain repertoire from germline constraints. These discoveries clarified how lymphocytes could generate an astronomically diverse antigen receptor repertoire from a finite set of genes.

In 1982 Allison and colleagues raised antisera against a cell surface molecule that could uniquely identify individual T-cell clones. A year later, Kappler and a consortium of colleagues demonstrated that these surface molecules were heterodimers composed of variable- and constant-region domains, just like immunoglobulin. Subsequently, Davis and Mak independently cloned the β -chain of the T-cell receptor (TCR). Initial confusion regarding the identity of the companion α -chain led to the realization that there were two mutually exclusive forms of TCR, $\alpha\beta$ and $\gamma\delta$.

■ PARATOPES AND EPITOPES ■

Immunoglobulins and TCRs both belong to the eponymous immunoglobulin superfamily (IgSF).¹⁻³ The study of antibodies precedes that of TCR by decades, hence much of what we know is based on knowledge first gleaned from the study of immunoglobulins.

Immunoglobulin-antigen interactions typically take place between the *paratope*, the site on the immunoglobulin at which the antigen binds, and the *epitope*, which is the site on the antigen that is bound. Thus lymphocyte antigen receptors do not recognize antigens, they recognize epitopes borne on those antigens. This makes it possible for the cell to discriminate between two closely related antigens, each of which can be viewed as a collection of epitopes. It also permits the same receptor to bind divergent antigens that share equivalent or similar epitopes, a phenomenon referred to as *cross-reactivity*.

Although both immunoglobulins and TCRs can recognize the same antigen, they do so in markedly different ways (Chapter 6). Immunoglobulins tend to recognize intact antigens in soluble form, and thus preferentially identify surface epitopes that can represent conformational structures that are noncontiguous in the antigen's primary sequence. TCRs recognize fragments of antigens that have been processed by a separate antigen-presenting cell and then bound to a major histocompatibility complex (MHC) class I or class II molecule (Chapter 5). This permits T cells to scan the internal, as well as the external, components of the antigen. Thus recognition of the antigen by the immune system often involves recognition of multiple epitopes on that antigen.

■ THE BCR AND TCR ANTIGEN RECOGNITION COMPLEX ■

While the ability of the surface antigen receptor to recognize antigen was appreciated early on, the mechanism by which the membrane-bound receptor relayed this antigen recognition event into the cell interior was not understood, since both B-cell receptor (BCR) and TCR cytoplasmic

Fig. 4.1 A two-dimensional model of an immunoglobulin G (IgG) molecule. The top H and L chains illustrate the composition of these molecules at a nucleotide level. The bottom chains illustrate the nature of the protein sequence. See text for further details.

domains are exceptionally short. This conundrum was solved when it was shown that BCR and TCR each associate noncovalently with signal transduction complexes: heterodimeric Ig α :Ig β for B cells and multimeric CD3 for T cells. Loss of function mutations in either of these complexes leads to cell death, which becomes clinically manifest as hypogammaglobulinemia in the case of B cells (Chapter 34), or severe combined immune deficiency (SCID) in the case of T cells (Chapter 35).

IMMUNOGLOBULINS AND TCR STRUCTURES

THE Ig DOMAIN, THE BASIC IgSF BUILDING BLOCK

Immunoglobulins consist of two heavy (H) and two light (L) chains (Fig. 4.1), where the L chain can consist of either a κ - or a λ -chain. TCRs consist of either an $\alpha\beta$ or a $\gamma\delta$ heterodimer. Each component chain contains two or more Immunoglobulin superfamily (IgSF) domains, each of which consists of two sandwiched β pleated sheets 'pinned' together by a disulfide bridge between two conserved cysteine residues (Fig. 4.2).¹ Considerable variability is allowed to the amino acids that populate the external surface of the IgSF domain and the loops that link the β strands. These solvent-exposed surfaces offer multiple targets for docking with other molecules.

Two types of IgSF domains, 'constant' (C) and 'variable' (V), are used in immunoglobulins and TCRs (Fig. 4.2). C-type domains, which are the most compact, have seven anti-parallel strands distributed as three strands in the first sheet and four strands in the second. Side chains positioned to lie between the two strands tend to be nonpolar in nature, creating a hydrophobic core of considerable stability. Indeed, V domains engineered to replace the conserved cysteines with serine residues retain their ability to bind antigen. V-type domains add two additional anti-parallel strands to the first sheet, creating a five-strand-four-strand

distribution. The two additional strands, which encode framework region 2 (FR2), are used to steady the interaction between heterodimeric V domains, allowing them to create a stable antigen-binding site.⁴

Each Ig and TCR chain contains only one NH₂-terminal V Ig domain. Ig H chains contain three or four COOH-terminal C domains, whereas both Ig L chains and all four TCR chains contain only one C domain each. H chains with three C domains tend to include a spacer *hinge* region between the first (C_{H1}) and second (C_{H2}) domains. Each V or C domain consists of approximately 110–130 amino acids, averaging 12 000–13 000 kDa. A typical L or TCR chain will thus mass approximately 25 kDa, and a three C-domain C γ H chain with its hinge will mass approximately 55 kDa.

IDIOTYPES AND ISOTYPES

Immunization of heterologous species with monoclonal antibodies (or a restricted set of immunoglobulins) has shown that immunoglobulins and TCRs contain both common and individual antigenic determinants. Individual determinants, termed *idiotypes*, are contained within V domains. Common determinants, termed *isotypes*, are specific for the constant portion of the antibody and allow grouping of immunoglobulins and TCRs into recognized classes, with each class defining an individual type of C domain. Determinants common to subsets of individuals within a species, yet differing between other members of that species, are termed *allotypes*, these define inherited polymorphisms that result from allelic forms of the genes.⁵

THE V DOMAIN

Early comparisons of the primary sequences of V domains identified three hypervariable intervals, termed complementarity-determining regions (CDRs), situated between four framework regions (FRs) of stable sequence (Fig. 4.1). The current definition of these regions

Fig. 4.2 Immunoglobulin superfamily (IgSF) domain structures. **(A)** A typical compact C domain structure. The β strands are labeled A through G. The sequence at the core is conserved and nonpolar. The external surface and the β -loops are available for docking and often vary in sequence. **(B)** A typical V domain structure. Two additional strands, C' and C'', have been added. Note the projection of the C-C' strands and loop away from the core.

integrates sequence diversity with three-dimensional structure.⁶ The international ImMunoGeneTics information system (IMGT), maintains an extremely useful website, <http://imgt.cines.fr>, which contains a large database of immunoglobulin and TCR sequences, as well as a multiplicity of software tools for their analysis.

ANTIGEN RECOGNITION AND THE F_{AB}

Studies of Ig structure were facilitated by the use of papain and pepsin to fragment IgG molecules. Papain digests IgG into two Fab fragments, each of which can bind antigen, and a single Fc fragment. Pepsin splits IgG into an Fc fragment and a single dimeric F(ab)₂ that can cross-link as well as bind antigens. The Fab contains one complete L chain in its entirety and the V and C_{H1} portion of one H chain (Fig. 4.1). The Fab can be further divided into a variable fragment (Fv) composed of the V_H and V_L domains, and a constant fragment (Fb) composed of the C_L and C_{H1} domains. Single Fv fragments can be genetically engineered to recapitulate the monovalent antigen-binding characteristics of the original, parent antibody.⁷ The extracellular domains of TCR $\alpha\beta$ and TCR $\gamma\delta$ correspond to Ig Fab.

KEY CONCEPTS

IMMUNOGLOBULIN AND T-CELL RECEPTOR (TCR) STRUCTURE

- >> Immunoglobulins and TCRs are heterodimeric proteins
- >> Immunoglobulins consist of two identical H and two L chains
- >> $\alpha\beta$ TCRs consist of one α - and one β -chain
- >> $\gamma\delta$ TCRs consist of one γ - and one δ -chain
- >> Each immunoglobulin (Ig) or TCR chain contains two or more domains with a characteristic β -barrel structure whose presence identifies a protein as a member of the immunoglobulin superfamily (IgSF)
- >> Each Ig and TCR chain contains a V-type IgSF domain that will form one-half of the antigen-binding site
- >> Each V domain contains three hypervariable intervals, known as complementarity-determining region (CDRs)
- >> The CDRs of paired heterodimer chains are juxtaposed to form the antigen-binding site
- >> The C domains of Ig H chains define the immunoglobulin class or subclass
- >> The two distal C IgH domains determine the effector function of the antibody.

EFFECTOR FUNCTION AND THE F_C

The Fc portion (Fig. 4.1) encodes the effector functions of the immunoglobulin. These functions are generally inflammatory reactions that include fixation of complement, activation of complement, and binding of antibody to Fc receptors on the surface of other cells. Each immunoglobulin class and subclass exhibits its own set of effector functions. For example, the IgG C_{H2} domain plays a key role in binding to class-specific Fc receptors on the surface of effector cells.⁸ Complement fixation is also focused on the C_{H2} domain. Both of these interactions are important in initiating the process of phagocytosis, in allowing certain subclasses to traverse the placenta, and in influencing the biologic functions of lymphocytes, platelets, and other cells.

G_M ALLOTYPE SYSTEM

A series of serologically defined genetic markers of the C domains of both H and L chains have been termed G_m for the gammaglobulin fraction of the serum in which they were first identified.⁹ Different allelic forms have been defined for C domains of the γ_1 , γ_2 , γ_3 , γ_4 , α_2 , and ϵ H chains and for the κ L chain. Associations between certain G_m allotypes and predisposition to develop certain diseases of immune function have been reported.

IMMUNOGLOBULIN CLASSES AND SUBCLASSES

The constant domains of the H chain define the class and subclass of the antibody. Table 4.1 lists the five major classes of immunoglobulins in humans and describes some of their physical and chemical features. Two

of the five major H chain classes, α and γ , have undergone duplication.¹⁰ IgG₁, IgG₂, IgG₃, and IgG₄ all have the same basic structural design and differ only in the primary sequence of their constant regions and in the location of their interchain disulfide bonds. The H chain in each of these subclasses is referred to as γ_1 , γ_2 , etc. IgA consists of the two subclasses, α_1 and α_2 . Table 4.2 compares the four subclasses of IgG, the two of IgA, and the classes of IgM, IgD, and IgE from the standpoint of their biologic functions. In humans, two L chain classes exist, κ and λ . No specific effector function has been identified for either L chain class.

IgM

IgM exists in monomeric, pentameric, and hexameric forms. The 8S monomeric 180 kDa IgM has the molecular formula μ_2L_2 . It is a minor fraction in serum, but in its transmembrane form IgM plays a key role

in B-cell development and function. The major form in serum is the 19S, 900 kDa pentameric IgM, which contains five subunits ($(\mu_2L_2)_5$) linked together by disulfide bridges, and by one molecule of an additional polypeptide chain, the J chain, which joins two of the subunits by a disulfide bridge.¹¹

IgM is the predominant immunoglobulin produced during the primary immune response. Occasionally, particularly in the case of carbohydrate Ags such as isohemagglutinins, it will remain the major or sole antibody class. IgM differs from most other immunoglobulins in having an extra C_H domain in place of a hinge.

IgM avidly fixes complement. This property is focused in C_H3, the homologue of IgG C_H2.¹² Although the valence of each μ_2L_2 subunit is 2, when binding to large protein antigens, five of the 10 antigen-binding sites in pentameric IgM appear blocked due to steric hindrance. As a consequence, the valence for large antigens is five.

IgG

IgG, the major immunoglobulin class, accounts for the bulk of serum antibody activity in response to most protein antigens. The four IgG subclasses are numbered in relation to their serum levels relative to each other, with IgG₁ predominant and IgG₄ the least common. IgG₁ and IgG₃ fix complement and bind phagocyte Fcγ receptors well, whereas IgG₂ fixes complement but binds Fcγ receptors more poorly. IgG₄ does not fix complement effectively in the native state, but has been reported to do so after proteolytic cleavage.¹³ IgG₁ and IgG₃ are most frequently elicited by viral antigens,¹⁴ IgG₂ by carbohydrates,¹⁵ and IgG₄ by helminthic parasites.¹⁶

IgA

Although IgA generally exists in a monomeric form (α_2L_2) in the serum, it can interact with J chain to form a polymer (α_2L_2)_{2,3}-J. Second in concentration to IgG in serum, IgA functions as the predominant form of immunoglobulin in mucosal secretions.¹⁷

Secretory IgA is largely synthesized by plasma cells located in, or originating from, mucosal tissues. In the secretions, the molecule usually exists in an alternative polymeric form with two subunits in association with the 70 kDa secretory component (α_2L_2)₂-SC. SC is synthesized by the epithelial cells that line the lumen of the gut. The complete function of SC remains uncertain, but it appears to serve as a receptor for IgA and may play a role in attracting IgA-bearing lymphocytes to the gut and other organs of secretion. It also appears to render the secretory IgA complex more resistant to proteolytic digestion.

IgE

IgE is largely found in extravascular spaces. Its plasma turnover is rapid, with a half-life of about 2 days. IgE antibodies help protect the host from parasitic infections. However, in westernized, affluent societies, IgE is primarily associated with allergy. Through their interaction with Fcε receptors on mast cells and basophils, IgE antibodies, in the presence of antigens, induce the release of histamine and various other vasoactive substances. These factors are responsible for clinical manifestations of various allergic states.¹⁸

IgD

Although the H chain of IgD can undergo alternative splicing to a secretory form, IgD serum antibodies in human are uncommon and are absent in the serum of mice and primates. Instead, IgD is typically found in association with IgM on the surface of mature lymphocytes. The appearance of IgD is associated with the transition of a B lymphocyte from a cell that can be tolerized to antigen to a cell that will respond to antigen with the production of antibody (Chapter 8).

TCR αβ AND γδ

As members of the IgSF, TCR α-, β-, γ-, and δ-chains share a number of structural similarities with immunoglobulin. Each chain has a leader peptide, an extracellular, a transmembrane, and an intracytoplasmic interval. The extracellular interval can be divided into three domains: a polymorphic V domain encoded by VJ (α- and γ-chains) or VDJ (β- and δ-chains) gene segments, a C domain, and a hinge region.¹⁹ The hinge

region typically contains an extra cysteine (none in γ-chains encoded by Cγ2) that forms a disulfide bond with the other partner of the heterodimer. The transmembrane domains all include a lysine and some contain an arginine residue that facilitate the association of the TCR heterodimer with components of the CD3 signal transduction complex, each of which has a matching negatively charged residue in its own transmembrane portions (see below). The intracytoplasmic domains are tiny and play a minimal role in signal transduction.

TCR αβ

The TCR α- and β-chains are glycoproteins with molecular weights that vary from 42 to 45 kDa, depending upon the primary amino acid sequence and the degree of glycosylation. Deglycosylated forms have a molecular mass of 30–32 kDa. These chains share a number of invariant residues in common with immunoglobulin heavy and light chains, in particular residues that are thought to be important for interactions between heavy and light chains. The structures of several partial or full-length TCRs have been solved by X-ray crystallography (Fig. 4.3).^{20–22} In general, the structure of the TCR αβ heterodimer is similar, but not identical, to that of an Ig Fab fragment.

TCR γδ

The TCR γ- and δ-chains are glycoproteins with a more complex molecular size pattern than α- and β-chains. TCRs that use the Cγ1 gene segment, which contains a cysteine-encoding exon, are disulfide-linked (molecular weight 36–42 kDa). TCRs that use Cγ2 exist in two nondisulfide-linked forms, one of 40–44 kDa and one of 55 kDa.²³ The differences in molecular size are due to variability of both N-linked glycosylation and primary amino acid sequence. The 55 kDa form uses a Cγ2 allele that contains three (rather than two) exons encoding the connecting piece, as well as more N-linked carbohydrate. The functional implication of three different TCR γ-chain isoforms, if any, is unknown. The TCR δ-chain is more straightforward, being 40–43 kDa in size and containing two sites of N-linked glycosylation. The overall architecture of the γδ TCR closely resembles that of αβ TCRs and antibodies, although the angle between the V and C domains, known as the elbow angle, appears more acute.

LIGAND RECOGNITION

Although TCR αβ T cells primarily recognize peptide–MHC complexes (pMHC) (Fig. 4.3; Chapters 5 and 7), other types of ligands exist. For example, some αβ TCRs can bind nonpeptidic antigens (atypical antigens) that are bound to nonclassic MHC molecules. Many γδ T cells recognize atypical antigens that may or may not be associated with an antigen-presenting molecule. Finally, many αβ TCRs bind superantigens (SAG) in a predominantly Vβ-dependent fashion (Chapter 6).

BINDING TO pMHC

TCRs recognize peptide antigens bound to the binding groove of MHC-encoded glycoproteins (Fig. 4.3). TCR recognition of pMHC requires a trimolecular complex in which all the components (antigen, MHC, and TCR) contact one another.^{20–22} Thus, recognition is highly influenced by polymorphisms in the MHC molecule (Chapter 5). As in the case of Ig, TCR CDR1 and CDR2 are encoded in the germline V

Fig. 4.3 Backbone representation of murine $\alpha\beta$ T-cell receptor (TCR) bound to murine major histocompatibility complex (MHC) class I and an octamer peptide. The TCR is above. The $V\alpha$ CDR1 and CDR2 are magenta, $V\beta$ CDR1 and CDR2 are blue, both CDR3s are green, and the $V\beta$ HV4 is orange. β_2M refers to β_2 -microglobulin. The peptide is in green, and the NH_2 -terminal and $COOH$ -terminal residues are designated P1 and P8. (From Garcia KC, Degano M, Stanfield RL, et al. An alphabeta T cell receptor structure at 2.5 Å and its orientation in the TCR-MHC complex. *Science* 1996; 274: 209–219. Reprinted with permission from AAAS.)

regions, whereas CDR3 is formed at the junction of the V gene with a J gene segment (TCR α and γ) or D and J gene segments (TCR β - and δ -chains).²⁴ $V\beta$ also has a fourth region of variability near the other CDRs, hypervariable region 4 (HV4) or CDR4, which can participate in SAg binding.

The co-crystallization of different combinations of soluble TCR $\alpha\beta$ interacting with MHC class I bound to antigen peptide (pMHC) has made it possible to directly address the manner in which antigen recognition occurs (Fig. 4.3).^{20–22} The TCR $\alpha\beta$ combining site is relatively flat, allowing it to interact with a rather broad surface at the point of contact with pMHC.

The TCR footprint on the pMHC complex often occurs in a diagonal across the MHC antigen-binding groove, with TCR $V\alpha$ positioned over the MHC α_2 helix and TCR $V\beta$ overlying the MHC α_1 helix. This geometry would permit consistent access of the CD8 co-receptors to the MHC class I molecule. The CDR1 and CDR2 loops, which are entirely encoded by germline sequence, tend to interact more with the MHC molecule; whereas the CDR3 loops, which are composed of both germline and somatic (N-region) sequence, appear to dominate the interaction with MHC-bound peptide.

The binding of TCR to pMHC appears to be driven by enthalpy. That is, binding increases the stability of the CDR loops, especially the CDR3s. These results have led to the suggestion that initial binding focuses on the interaction between CDRs 1 and 2 and the MHC. After this initial recognition, the CDR3s change their shape to maximize the area of contact. Conformational flexibility, or ‘induced fit,’ would allow TCRs to sample many similar pMHC complexes rapidly, stopping only when their CDR3s are able to stabilize the interaction.

TCR-BINDING AFFINITY

The affinity with which the TCR ultimately binds its ligand is a critical determinant of T-cell activation. It is, however, only one factor in determining the overall *avidity* of the interaction, since other cell surface molecules of the T cell (e.g., CD4, CD8, CD2, and various integrins) bind to cell surface molecules on the antigen-bearing cell to stabilize cell–cell TCR–ligand interactions. Furthermore, since both the TCR and the pMHC ligand are surface membrane proteins, each T cell can provide multiple TCR in the same plane that can bind multiple pMHC molecules on the surface of the antigen-presenting cell. This makes binding of TCR to pMHC functionally multivalent, enhancing the apparent affinity of the interaction.

ATYPICAL ANTIGENS

Some $\alpha\beta$ T cells can recognize lipid antigens when they are complexed with members of the CD1 family.²⁵ The interaction of TCR $\alpha\beta$ with CD1 resembles that of TCR $\alpha\beta$ with MHC class I. Allelic polymorphism in CD1 is limited, which theoretically would restrict the range of lipid antigens that can be bound.

Rather than binding to a single groove on the MHC, lipids attach themselves to one of several hydrophobic pockets that can be found on the surface of CD1. Pocket volume can range from 1300 Å³ to 2200 Å³. The number and length of the pockets differ between the various CD1 isoforms. For example, CD1b has three pockets that share a common portal of entry, as well as a fourth pocket that connects two of the three pockets to each other. This connecting pocket permits the insertion of lipids with a long alkyl chain, such as mycobacterial mycolic acid.

Antigen recognition by $\gamma\delta$ TCRs resembles recognition of intact antigens by antibodies more closely than recognition of pMHC by $\alpha\beta$ TCR.²⁶ $\gamma\delta$ TCRs can recognize protein antigens, such as nonclassical MHC molecules and viral glycoproteins, as well as small, phosphate- or amine-containing compounds, such as pyrophosphomonoesters from mycobacteria and alkylamines.

Binding to nonpeptide antigens plays an important role in the biology of $\gamma\delta$ T cells. About 5% of peripheral blood T cells bear $\gamma\delta$ TCRs, and most of these are encoded by $V\gamma 9J\gamma P$ and $V\delta 2^*$ gene segments. (In an alternative nomenclature, $V\gamma 9$ is known as $V\gamma 2$ and $J\gamma P$ as $J\gamma 1.2$. See the IMGT database at <http://imgt.cines.fr/>.) These $V\gamma 9J\gamma PV\delta 2^*$ TCRs recognize nonpeptide pyrophosphate- or amine-containing antigens, such as pyrophosphomonoesters from mycobacteria or isobutylamine from various sources.²⁶ Other common naturally occurring small phosphorylated metabolites that stimulate $\gamma\delta$ T cells include 2,3-diphosphoglyceric acid, glycerol-3-phosphoric acid, xylose-1-phosphate, and ribose-1-phosphate. In addition to mycobacteria, $V\gamma 9J\gamma PV\delta 2^*$ T-cell populations are seen to expand in response to listeriosis, ehrlichiosis, leishmaniasis, brucellosis, salmonellosis, mumps, meningitis, malaria, and toxoplasmosis.

The atypical antigens do not require antigen processing and are not co-recognized with known antigen-presenting molecules. Although MHC presentation is not necessary, cell-cell contact is required for stimulation. This suggests either that the small molecules are being presented by non-MHC molecules or that co-stimulation from neighboring cells is needed for proper $\gamma\delta$ T-cell activation.

SUPERANTIGENS

SAGs are a special class of TCR ligands that have the ability to activate large fractions (5–20%) of the T-cell population. Activation requires simultaneous interaction between the SAG, the TCR $V\beta$ domain, and an MHC class II molecule on the surface of an antigen-presenting cell.²⁷

Unlike conventional antigens, SAGs do not require processing to allow them to bind class II molecules or activate T cells. Instead of binding to the peptide antigen-binding groove, SAGs bind to polymorphic residues on the periphery of the class II molecule. And, instead of binding to TCR β CDR3 residues, SAG bind to polymorphic residues in CDR1, CDR2, and HV4. Soluble TCR β -chains can also bind the appropriate SAG in the absence of a TCR α -chain. As a consequence, although SAG link the TCR to the MHC, the T-cell responses are not 'MHC-restricted' in the conventional sense, since a T cell with the appropriate $V\beta$ will respond to a SAG bound to a variety of polymorphic class II molecules.

IMMUNOGLOBULIN AND TCR GENE ORGANIZATION

The component chains of immunoglobulins and TCRs are each encoded by a separate multigene family.^{28,29} The paradox of variability in the V region in conjunction with a nearly invariable constant region was resolved when it was shown that immunoglobulin V and C domains are encoded by independent elements, or gene segments, within each gene family. That is, more than one gene element is used to encode a single polypeptide chain. For example, while κ constant domains are encoded by a single $C\kappa$ exon in the κ locus on chromosome 2,³⁰ κ variable domains represent the joined product of $V\kappa$ and $J\kappa$ gene segments (Fig. 4.1).

KEY CONCEPTS

FEATURES COMMON TO IMMUNOGLOBULIN (IG) AND T-CELL RECEPTOR (TCR) GENES

- >> Ig and TCR variable domains are created by site-specific V(D)J recombination
- >> Each receptor is assembled in a stepwise fashion:
 - Immunoglobulins: $D_H \rightarrow J_H$; $VH \rightarrow D_HJ_H$; cytoplasmic μ -chain expression; $V\kappa \rightarrow J\kappa$ and, if needed, $V\lambda \rightarrow J\lambda$; surface IgM expression
 - TCR $\alpha\beta$: $D\beta \rightarrow J\beta$; $V\beta \rightarrow D\beta J\beta$; cytoplasmic β -chain expression; $V\alpha \rightarrow J\alpha$; surface $\alpha\beta$ TCR expression
- >> In developing lymphocytes, CDRs1 and 2 contain exclusively germline sequence, whereas CDR3 is created by the (V[D]J) joining reaction and often includes nongermine sequence:
- >> CDR-H3, CDR-B3, and CDR-D3 are the most variable components of IgM, TCR $\alpha\beta$, and TCR $\gamma\delta$, respectively
- >> The antigen-binding site is a product of a nested gradient of diversity. Conserved framework regions flank CDR1 and CDR2, which in turn surround the paired CDR3 intervals that form the center of the antigen-binding site
- >> Starting with a small set of individual gene segments, combinatorial gene segment rearrangement, combinatorial association of heavy and light chains, and mechanisms of junctional diversity generate a broad repertoire of antigen-binding structures
- >> The variability of the Ig and TCR repertoires is restricted during perinatal life, limiting the immune response of the infant

KEY CONCEPTS

FEATURES SPECIFIC TO IG GENES

- >> Variable-domain somatic hypermutation (SHM) permits affinity maturation
- >> Class switch recombination (CSR) allows replacement of an upstream C domain by a downstream one, altering effector function while maintaining antigen specificity

V_L gene segments typically contain their own promoter, a leader exon, an intervening intron of ~ 100 nucleotides, an exon that encodes the first three framework regions (FR1, 2, and 3), the first two CDRs in their entirety, the amino-terminal portion of CDR 3, and a recombination signal sequence. A J_L (J for joining) gene segment begins with its own recombination signal, the remaining portion of CDR 3, and the complete FR4 (Fig. 4.1).

(Use of the same abbreviation, V_L , for both the complete variable domain of an immunoglobulin peptide chain and for the gene segment that encodes only a portion of that same variable domain is the result of historic precedent. It is unfortunate that one must depend on the context of the

Fig. 4.4 Rearrangement events in the human κ locus. V, variable region; J, joining region; C, constant region of the κ light chain. See text for further description.

surrounding text in order to determine which V region of the antibody is being discussed. The same holds true for the use of J to represent both the J gene segment and the J joining protein.)

The creation of a V domain is directed by the recombination signal sequences (RSS) that flank the rearranging gene segments. Each RSS contains a strongly conserved 7-basepair, or heptamer, sequence (e.g., CACAGTG) that is separated from a less well-conserved 9-basepair, or nonamer, sequence (e.g., ACAAAACCC) by either a 12- or 23-basepair spacer. For example, V_{κ} gene segments have a 12-basepair spacer and J_{κ} elements have a 23-basepair spacer. These spacers place the heptamer and nonamer sequences on the same side of the DNA molecule, separated by either one or two turns of the DNA helix. A one-turn recombination signal sequence (12-basepair spacer) will preferentially recognize a two-turn signal sequence (23-basepair spacer). This helps prevent wasteful V-V or J-J rearrangements.

Initiation of the V(D)J recombination reaction requires recombination-activating genes 1 and 2 (RAG-1 and RAG-2). These genes are only expressed in developing lymphocytes.³¹ RAG-1 and RAG-2 act by precisely introducing a DNA double-strand break between the terminus of the rearranging gene segment and its adjacent recombination signal sequence (Fig. 4.5). These breaks are then repaired by ubiquitously expressed components of a DNA repair process that is known as nonhomologous end-joining (NHEJ). Lack-of-function mutations in NHEJ proteins yield susceptibility to DNA damage in all cells of the body.

The NHEJ process creates precise joins between the RSS ends, and imprecise joins of the coding ends. TdT, which is only expressed in

lymphocytes, adds nongermline-encoded nucleotides (N nucleotides) to the coding ends of the recombination product.

Lymphoid-specific expression of RAG-1 and RAG-2 limits V(D)J recombination to B and T lymphocytes. However, to ensure that TCR genes are rearranged to completion only in T cells and immunoglobulin genes are rearranged to completion only in B cells, V(D)J recombination is further regulated by limiting the accessibility of the appropriate gene segments to the specific lineage as well as to the specific stage of development. For example, H chain genes are assembled before L chains.

RAG-1 and RAG-2 cooperatively associate with 12- and 23-basepair RSSs and their flanking coding gene segments to form a synaptic complex. Typically, the initial event will be recognition of the nonamer sequence of a 12-basepair spacer RSS by RAG-1. RAG-1 binding to the heptamer provides specificity. RAG-2 does not bind DNA independently, but does make contact with the heptamer when in a synaptic complex with RAG-1. Binding of a second RAG-1 and RAG-2 complex to the 23-basepair, two-turn RSS permits the interaction of the two synaptic complexes to form what is known as a paired complex. Creation of this paired complex is facilitated by the actions of the DNA-bending proteins HMG1 and HMG2.

After paired complex assembly, the RAG proteins single strand cut the DNA at the heptamer sequence. The 3' OH of the coding sequence ligates to 5'phosphate and creates a hairpin loop. The clean-cut ends of the signal sequences enable formation of precise signal joints. However, the hairpin junction created at the coding ends must be resolved by re-nicking the DNA, usually within four to five nucleotides from the end of

Fig. 4.5 VDJ recombination. Lymphoid-specific RAG-1 and RAG-2 bind to the recombination signal sequences (RSS) flanking V, D, or J gene segments, juxtapose the sequences, and introduce precise cuts adjacent to the RSS. Components of the nonhomologous end joining repair pathway subsequently unite the cut RSS to form a signal joint, and the coding sequences of the rearranging gene segments to form a coding joint.

the hairpin. This forms a 3' overhang that is amenable to further modification. It can be filled in via DNA polymerases, nibbled, or serve as a substrate for TdT-catalyzed N addition. DNA polymerase μ , which shares homology with TdT, appears to play a role in maintaining the integrity of the terminus of the coding sequence.

The cut ends of the coding sequence are then repaired by the nonhomologous end joining proteins. NHEJ proteins involved in V(D)J recombination include Ku70, Ku80, DNA-PKcs, Artemis, XRCC4, and ligase 4. Deficiency of any one of these proteins creates sensitivity to DNA breakage and can lead to a SCID phenotype (Chapter 35).

Ku70 and Ku80 form a heterodimer (Ku) that directly associates with DNA double-strand breaks to protect the DNA ends from degradation, permit juxtaposition of the ends to facilitate coding end ligation, and help recruit other members of the repair complex. DNA-PKcs phosphorylates Artemis, inducing an endonuclease activity that plays a role in the

opening of the coding joint hairpin. Thus absence of DNA-PKcs or Artemis inhibits proper coding joint formation. Signal joint formation is normal in Artemis deficiency, but it is impaired in the absence of DNA-PKcs. This suggests an additional, as yet undefined, role for DNA-PKcs. Finally, XRCC4 and ligase 4 help rejoin the ends of the broken DNA.

Depending on the transcriptional orientation of the rearranging gene segments, recombination may result in either inversion or deletion of the intervening DNA (Fig. 4.4). The products of inversion remain in the DNA of the cell, whereas deletion leads to the loss of the intervening DNA. The increased proximity of the V promoter to the C domain enhancers promotes the subsequent transcription of the Ig gene product.

THE κ LOCUS

The κ locus is located on chromosome 2p11.2. It contains five J κ and 75 V κ gene segments upstream of C κ (Fig. 4.6). The V κ gene segments can be grouped into six different families of varying size.³⁰ Each family is comprised of gene segments that share extensive sequence and structural similarity.^{32,33}

One-third of the V κ gene segments contain frameshift mutations or stop codons that preclude them from forming functional protein, and of the remaining sequences fewer than 30 of the V κ gene segments have actually been found in functional immunoglobulins. Each of these active V κ gene segments has the potential to rearrange to any one of the five J κ elements, generating a potential repertoire of more than 140 distinct VJ combinations. Even more diversity is created at the site of gene segment joining. The terminus of each rearranging gene segment can undergo a loss of 1–5 nucleotides during the recombination process. In human, but not mouse, N addition can either replace some or all of the lost nucleotides or can be inserted in addition to the original germline sequence.³⁴ Each codon created by N addition increases the potential diversity of the repertoire 20-fold. Thus, the initial diversification of the κ repertoire is focused at the VJ junction that defines CDR-L3.

THE λ LOCUS

The λ locus, on chromosome 22q11.2, contains four functional C λ exons, each of which is associated with its own J λ (Fig. 4.6). The V λ genes are arranged in three distinct clusters, each containing members of different V λ families.³⁵ Depending on the individual haplotype, there are approximately 30–36 potentially functional V λ gene segments and an equal number of pseudogenes.

In addition to normal κ and λ peptides, H chains can also form a complex with unconventional λ light chains, known as surrogate or pseudo light chains (Ψ LC). The genes encoding the Ψ LC proteins, λ 14.1 (λ 5) and V_{preB}, are located within the λ light-chain locus on chromosome 22. Together, these two genes create a product with considerable homology to conventional λ light chains. The λ 14.1 gene contains J λ and C λ -like sequences and the V_{preB} gene includes a V λ -like sequence. A critical difference between these unconventional Ψ LC genes and other L chains is that λ 14.1 and V_{preB} gene rearrangement is not required for Ψ LC expression.

THE H-CHAIN LOCUS

The H-chain locus, on chromosome 14q32.33, is considerably more complex than the κ and λ loci. There are ~ 80 V_H gene segments near the telomere of the long arm of chromosome 14.³⁶ Of these, approximately 39

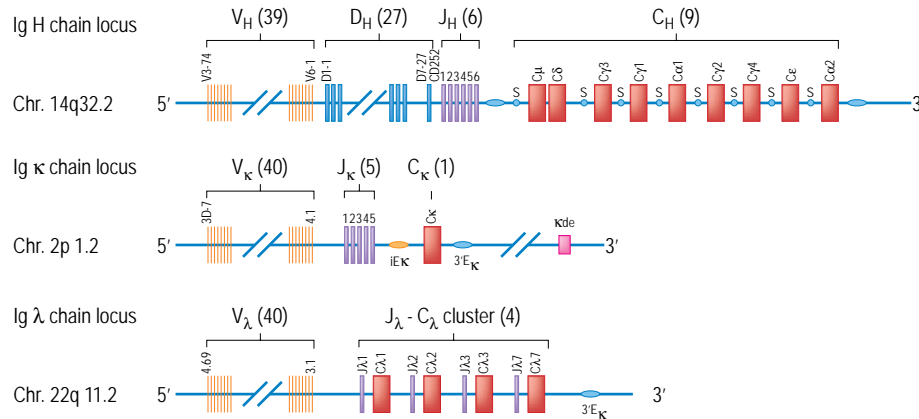

Fig. 4.6 Chromosomal organization of the immunoglobulin (Ig) H, κ , and λ gene clusters. The typical numbers of functional gene segments are shown. The κ gene cluster includes a κ -deleting element that can rearrange to sequences upstream of C_κ in cells that express λ -chains, reducing the likelihood of dual κ and λ light-chain expression. These maps are not drawn to scale.

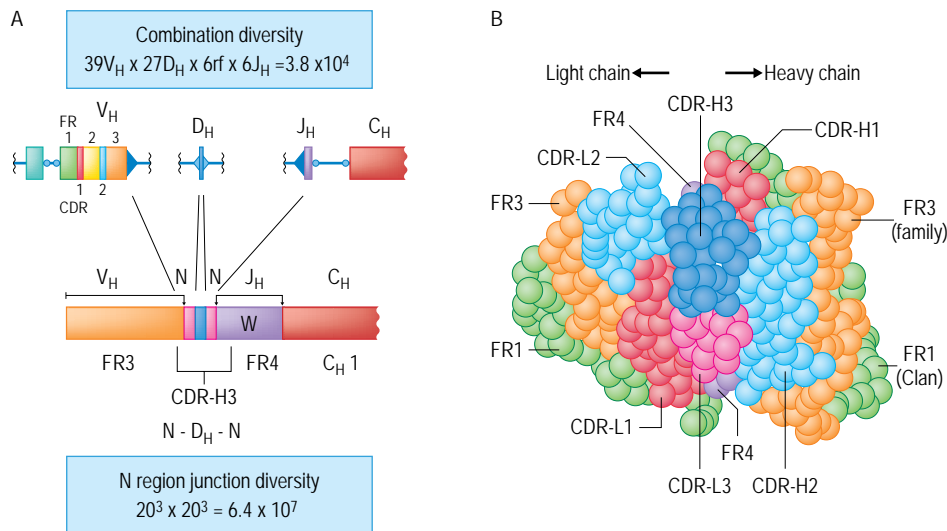

Fig. 4.7 The antigen-binding site is the product of a nested gradient of diversity. (A) VDJ rearrangement yields 3800 different combinations. The CDR-H3 sequence contains both germline V, D, and J sequence, as well as nongermine N nucleotides. The addition of nine N nucleotides on either side of the D gene segment yields 64 million different combinations. (B) The antigen-binding site is created by the juxtaposition of the three complementarity-determining regions (CDRs) of the H chain and the three CDRs of the light chain. The view is looking into the binding site as an antigen would see the CDRs. The V_H domain is on the right side. The central location of CDR-H3, which due to N addition is the focus for repertoire diversity, is readily apparent.

are functional and can be grouped into seven different families of related gene segments. Adjacent to the most centromeric V_H , $V6-1$, are 27 D_H (D for diversity) gene segments (Fig. 4.6)³⁷ and six J_H gene segments. Each V_H and J_H gene segment is associated with a two-turn recombination signal sequence, which prevents direct V–J joining. A pair of one-turn recombination signal sequences flanks each D_H . Recombination begins with the joining of a D_H to a J_H gene segment, followed by the joining of a V_H element to the amino-terminal end of the DJ intermediate. The V_H gene segment contains FR1, -2, and -3, CDR1 and -2, and

the amino-terminal portion of CDR3; the D_H gene segment forms the middle of CDR3; and the J_H element contains the carboxy-terminus of CDR3 and FR4 in its entirety (Fig. 4.1). Random assortment of one of ~50 active V_H and one of 27 D_H with one of the six J_H gene segments can generate up to 10^4 different VDJ combinations (Fig. 4.7).

Although combinatorial joining of individual V, D, and J gene segments maximizes germline-encoded diversity, the major source of variation in the pre-immune repertoire is focused on the CDR-H3 interval which is created by VDJ joining (Fig. 4.7). First, D_H gene segments can

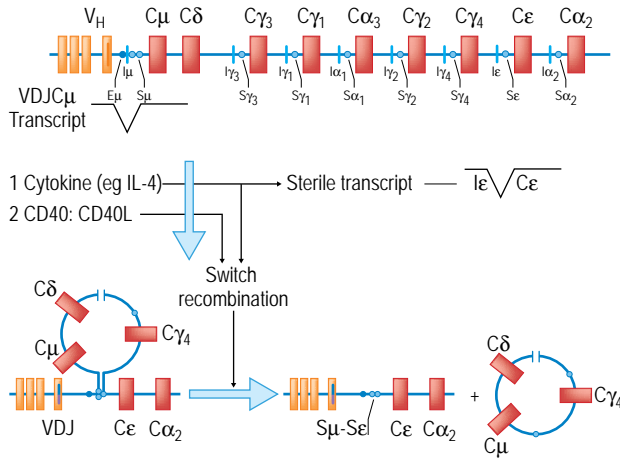

Fig. 4.8 Immunoglobulin H-chain class switching. The molecular events involved in switching from expression of one class of immunoglobulin to another are depicted. At the top is the gene organization during μ -chain synthesis. At the bottom a class switch recombination event has resulted in the deletion of the intervening DNA. Exposure to the appropriate cytokine or T-cell:B-cell interaction through the CD40:CD40L pathway results in activation of the I exon that yields a sterile epsilon transcript ($I\epsilon$ - $C\epsilon$) (Chapter 8). The CD40:CD40L interaction is necessary for the subsequent replacement of C_μ by another constant gene (in this case, $C\epsilon$). The S loci indicate switch-specific recombination signals.

rearrange by either inversion or deletion, and thus have the potential to be read backwards as well as forwards. Each D_H can be spliced and translated in each of the three potential reading frames. Thus, each D_H gene segment has the potential to encode six different peptide fragments. Second, the terminus of each rearranging gene segment can undergo a loss of one or more nucleotides during the recombination process. Third, the rearrangement process proceeds through a step that creates a hairpin ligation between the 5' and 3' termini of the rearranging gene segment. Nicking to resolve the hairpin structure leaves a 3' overhang that creates a palindromic extension, termed a P junction. Fourth, nongermline-encoded nucleotides (N regions) can be used to replace or add to the original germline sequence. Every codon that is added by N-region addition increases the potential diversity of the repertoire 20-fold. N regions can be inserted both between the V and the D, and between the D and the J. Together, the imprecision of the joining process and variation in the extent of N addition permit generation of CDR-H3s of varying length and structure. As a result, more than 10^{10} different H-chain VDJ junctions, or CDR-H3s, can be generated at the time of gene segment rearrangement. Together, somatic variation in CDR3, combinatorial rearrangement of individual gene segments, and combinatorial association between different L and H chains yields a potential pre-immune antibody repertoire of greater than 10^{16} antibody repertoire of greater different immunoglobulins.

CLASS SWITCH RECOMBINATION

Located downstream of the VDJ loci are nine functional C_H gene segments (Fig. 4.8).¹⁰ The C_H consist of a series of exons, each encoding a separate domain, hinge, or terminus. All C_H genes can undergo alternative splicing to generate two different types of carboxy termini: either a membrane

terminus that anchors immunoglobulin on the B lymphocyte surface, or a secreted terminus that occurs in the soluble form of the immunoglobulin. With the exception of $C_H1\delta$, each C_H1 constant region is preceded by both an exon that cannot be translated (an I exon) and a region of repetitive DNA termed the switch (S) region. Through recombination between the C_μ switch region and one of the switch regions of the seven other H chain constant regions (a process termed *class switching* or *CSR*), the same VDJ heavy-chain variable domain can be juxtaposed to any of the H-chain classes (Fig. 4.8).¹⁰ Thus, the system can tailor both the receptor and the effector ends of the antibody molecule to meet a specific need.

SOMATIC HYPERMUTATION

A final mechanism of immunoglobulin diversity is engaged only after exposure to antigen. With T-cell help, the variable domain genes of germinal center lymphocytes undergo *somatic hypermutation* (SHM) at a rate of up to 10^{-3} changes per basepair per cell cycle. SHM is correlated with transcription of the locus and current studies suggest that at least two separate mechanisms are involved. The first mechanism targets mutation hot spots with the RGYW (purine/G/pyrimidine/A) motif³⁸ and the second mechanism incorporates an error-prone DNA synthesis that can lead to a nucleotide mismatch between the original template and the mutated DNA strand.³⁹ SHM allows affinity maturation of the antibody repertoire in response to repeated immunization or exposure to antigen.

ACTIVATION-INDUCED CYTIDINE DEAMINASE

Activation-induced cytidine deaminase (AID) plays a key role in both CSR and SHM.^{31, 40} AID is a single-strand DNA (ssDNA) cytidine deaminase that can be expressed in activated germinal center B cells. Transcription of an immunoglobulin V domain or of the switch region upstream of the C_H1 domain opens the DNA helix to generate ssDNA that can then be deaminated by AID to form mismatched dU/dG DNA basepairs. The base excision repair protein uracil DNA glycosylase (UNG) removes the mismatched dU base, creating an abasic site. Differential repair of this lesion leads to either SHM or CSR. The mismatch repair proteins MSH2 and MSH6 can also bind and process the dU:dG mismatch. Deficiencies of AID and UNG underlie some forms of the hyper-IgM syndrome (Chapter 34).

DIVERSITY AND CONSTRAINTS ON IMMUNOGLOBULIN SEQUENCE

In theory, combinatorial rearrangement of V(D)J gene segments, combinatorial association of H and L chains, flexibility in the site of gene segment joining, N-region addition, P junctions, hypermutation, and class switching can create an antibody repertoire the diversity of which is limited only by the total number of B cells in circulation at any one time. In practice, constraints and biases on both the structure and sequence of the antibody repertoire are apparent.

The representation of individual V gene elements is nonrandom. Among V_k and V_H elements, half of the potentially functional V gene elements contribute minimally to the expressed repertoire. Among V_L elements these restrictions are even greater, with three gene segments contributing to half of the expressed repertoire.

Fig. 4.9 Chromosomal organization of the T-cell receptor (TCR) $\alpha\delta$, β , and γ gene clusters. Typical numbers of functional gene segments are shown. These maps are not drawn to scale.

Particular patterns of amino acid composition in the sequences of the V domains create predictable canonical structures for several of the hypervariable regions. In κ chains, CDR2 is found in a single canonical structure, whereas four structures are possible for CDR1.⁴¹ In the H chain, germline CDR1 and CDR2 elements encode one of three or one of five distinct canonical structures, respectively.⁴² Preservation of these key amino acids during affinity maturation tends to maintain the canonical structure of CDR1 and CDR2 even while they are undergoing SHM.⁴³

The enhanced sequence diversity of the CDR3 region is mirrored by its structural diversity. Few canonical structures have been defined for the H-chain CDR3, and even in κ chains 30% of the L chain CDR3 can be quite variable. However, at the sequence level there is a preference for tyrosine and glycine residues in the H-chain CDR3, which reflects both preferential use of only one of the six potential D_H reading frames as well as selection during development.⁴⁴

THE TCR $\alpha\delta$ -CHAIN LOCUS

The α and δ loci are located on chromosome 14q11-12. This region is unusual in that the gene segments encoding the two different TCR chains are actually intermixed (Fig. 4.9). There are 38–40 V_α , 5 V_α/V_δ , and 50 J_α functional gene segments, as well as one C_α gene in the locus.⁴⁵ Variation in numbers does occur between individuals. There are no D_α segments.

The δ locus lies between the V_α and J_α gene segments. There are three committed V_δ , five V_α/V_δ , three D_δ , and three J_δ gene segments, as well as one C_δ gene. V_δ lies 3' of C_δ , and thus must rearrange by inversion. Although V region use by α and δ chains is largely independent of one another, this unusual gene organization is accompanied by sharing of five

V gene segments. For example, V_δ can rearrange to either D_δ/J_δ or to J_α elements, and thus can serve as the V region for both $\gamma\delta$ and $\alpha\beta$ TCRs.

In the large majority of $\alpha\beta^+$ T cells analyzed, the α -chain on both chromosomes has rearranged. This occurs by the rearrangement of the 5' recombination signal sequence δ Rec to a pseudo-J segment, ΨJ_α , at the beginning of the J_α cluster (Fig. 4.9) as well as by the subsequent rearrangement of V_α to J_α on both chromosomes. Both types of rearrangement delete all of the D_δ , J_δ , and C_δ genes, preventing co-expression of $\alpha\beta$ and $\gamma\delta$ TCRs.

THE TCR β -CHAIN LOCUS

The β locus is positioned at chromosome 7q35.⁴⁵ It contains 40–48 functional V_β genes, two D_β , two J_β clusters each containing six or seven gene segments, and two C_β genes (Fig. 4.9). There is one V_β immediately downstream of C_β , which rearranges by inversion. Each C_β is preceded by its own D_β – J_β cluster. There is no apparent preference for V_β gene rearrangement to either D_β – J_β cluster. D_β can rearrange to the J_β cluster or the D_β – J_β cluster. D_β can only rearrange to J_β gene segments. The two C_β segments differ by only six amino acids and are functionally indistinguishable from each other.

THE TCR γ -CHAIN LOCUS

The γ locus is located at chromosome 7p14-15.⁴⁵ There are four to six functional V_γ region segments intermixed with pseudogenes and two J clusters with a total of five J segments.⁴⁵ Each J cluster is 5' to its C region (Fig. 4.9). The V_γ segments have been divided into six families, although only V_γ 1 (nine members, five of them functional) and V_γ 2 (one member) encode functional proteins. The number of C_γ gene

KEY CONCEPTS

B-CELL RECEPTOR (BCR) AND CO-RECEPTORS

- >> The BCR–antigen complex consists of a membrane-bound immunoglobulin (Ig) that is responsible for antigen recognition and an Ig- α - β heterodimer that transduces the binding signal into the cell
- >> BCR engagement leads to the phosphorylation of tyrosines in the Ig- α - β immunoreceptor tyrosine-based activation motifs (ITAMs). This signal is then transmitted to one or more other intracellular signaling pathways
- >> Recognition of antigen by B lymphocytes can also involve binding of antigen complexed with C3d and IgG to additional B-cell co-receptors
- >> Binding of complexed antigen by individual co-receptors can lead to either positive or negative signals, each of which can influence the ultimate outcome of an antigen–B lymphocyte interaction
- >> Deficiency of the components of the BCR–antigen complex impairs B-cell development and can produce agammaglobulinemia

exons varies: C γ 1 has three, while there are two alleles of C γ 2 that have four and five, respectively. The first C γ exon encodes most of the extracellular portion of this region. The last C γ exon encodes the intracytoplasmic portion of the molecule. The middle exon(s) (one for C γ 1, two or three for C γ 2) encode the connecting piece, which does (C γ 1), or does not (C γ 2), include a cysteine. Since this cysteine can form a disulfide bond with another cysteine in the δ -chain, TCRs using C γ 1 contain a covalently linked γ - δ pair, while TCRs using C γ 2 do not.

The nomenclature of the human γ locus differs between laboratories and reports, and is extensively cross-referenced on the IMGT website (<http://imgt.cines.fr>).

ALLELIC EXCLUSION

Because of the inherently imprecise nature of coding joints, only one in three V(D)J rearrangements will be in-frame and capable of creating a functional protein.^{31, 46} Theoretically, one in nine cells might be expected to express two different Ig or TCR chains. However, almost all B cells express the functional products of only one IgH allele and one IgL allele, and mature $\alpha\beta$ T cells express only one functional TCR β gene. The process of limiting the number of receptors expressed by an individual cell is known as *allelic exclusion*.

Both stochastic and regulated models have been put forth to explain this process, but the precise mechanism remains unclear. The mechanism has been shown to be associated with the expression of an Ig or TCR product capable of transducing a signal. In pre-B cells, a functional μ H-chain associates with the surrogate light chain to form the pre-BCR. Similarly, in developing T-cell progenitors a productive TCR β -chain associates with pre-T α to form the pre-TCR. These preliminary antigen receptors signal to shut down RAG expression, promote cell division, and limit the accessibility of the IgH and TCR β loci to further

rearrangement while promoting the accessibility of the IgL and TCR α loci, respectively.

In pre-B cells, the κ locus is the first to rearrange, with λ rearrangement occurring in cells that have failed to produce a proper κ chain. Surface expression of an acceptable membrane-bound IgM BCR invokes the mechanism of allelic exclusion among the L-chain loci and promotes further maturation of the B cell.

Productive TCR α rearrangement in CD4⁺CD8⁺T-cell progenitors allows the expression of a functional TCR $\alpha\beta$ heterodimer. Unlike IgH and TCR β , TCR α does not undergo allelic exclusion at the level of gene rearrangement. Instead, in cells that express two functional TCR α alleles, one of the two alleles tends to pair preferentially with the one functional TCR β chain. This results in phenotypic allelic exclusion.

Allelic exclusion can be overcome by selection pressures. Cells that express self-reactive antigen receptors can downregulate IgH or TCR expression and reactivate gene rearrangement to replace one of the two offending chains. This process, termed *receptor editing*,⁴⁷ occurs most often in the IgL or TCR α loci, whose gene structures lend themselves to repeated rearrangement. Less commonly, the V_H in the H chain can be replaced by means of rearrangement to a cryptic RSS located at the terminus of the V_H gene segment.

B-CELL RECEPTOR COMPLEX: STRUCTURE AND FUNCTION

Although the ability of surface immunoglobulin to recognize antigen was appreciated very early, the mechanism by which membrane-bound immunoglobulin (mIg) transmitted an antigen recognition event to the cell took longer to understand. Specifically, as the predominant isotypes expressed on the surface of mature B cells, mIgM and mIgD, contain only three amino acid residues exposed to the cytoplasm, it was thought unlikely that these Ig heavy chains could function as signal transduction molecules by themselves. This presumption was eventually proved correct when it was shown that all membrane immunoglobulin isotypes associated noncovalently with a heterodimeric complex consisting of two transmembrane proteins, Ig- α and Ig- β , each of which is capable of transducing signals into the cell (Table 4.3).

MEMBRANE-BOUND IMMUNOGLOBULIN

Immunoglobulins mediate their effector functions as secreted products of plasma cells. However, as membrane-bound structures on mature B cells, immunoglobulins serve as the antigen recognition component of the BCR complex. Although all immunoglobulin classes can be expressed at the cell surface, the vast majority of circulating mature B cells coexpress membrane-bound IgM and IgD. Appropriate activation of a naïve IgM- and IgD-expressing B cell leads to plasma cell differentiation and antibody secretion. The membrane-bound forms of IgM and IgD are the product of alternative splicing of the immunoglobulin transcript at the 3', or carboxy-terminus, of the heavy chain (Fig. 4.10). The two membrane exons encode transmembrane hydrophobic stretch of amino acids and an evolutionary conserved cytoplasmic tail encoding lysine, valine, and lysine.

Table 4.3 The B-cell receptor (BCR) and its co-receptor molecules

Molecule	M _r	Chromosome	Function
BCR			
mIgM (μ ₂ L ₂)	180 000	14 (IgH; 14q.32) 2 (Igκ; 2p12) 22 (Igλ; 22q11.2)	Antigen recognition
Ig-α	47 000	19 (19q13.2)	Signal transducer
Ig-β	37 000	17 (17q23)	Signal transducer
Co-receptors			
CD21	140 000	1 (1q32)	Activating co-receptor Ligand for C3d, EBV, CD23
CD19	95 000	16 (16p11.2)	Activating co-receptor Signal transducer
FcγRIIB	40 000	1 (1q23-24)	Inhibitory co-receptor Low-affinity receptor for immunoglobulin G
CD22	140 000	19 (19q13.1)	Inhibitory co-receptor Adhesion molecule Signal transducer

mIgM, membrane-bound immunoglobulin M.

Fig. 4.10 Membrane and secretory immunoglobulin (Ig)M are created by alternative splicing. Alternative splicing of the Cμ carboxy-terminal exons results in mRNA transcripts encoding either secreted IgM (μ_s RNA) or membrane-bound IgM (μ_m RNA).

SIGNAL TRANSDUCTION AND THE IG-α/β (CD79A/CD79B) HETERODIMER

The heterodimeric signal transduction component of the BCR complex that associates with mIg has been designated CD79. It is composed of Ig-α (CD79a) and Ig-β (CD79b). CD79 is responsible for transporting mIg to the cell surface and for transducing BCR signals into the cell.^{48, 49}

CD79a/Ig-α is encoded by *CD79a/MB-1* (chromosome 19q13.2) as a 226-amino-acid glycoprotein of approximately 47 kDa. The exact molecular weight depends on the extent of glycosylation. *CD79b/B29*

(chromosome 17q23) encodes CD79b/Ig-β, which is a 229-amino-acid glycoprotein of approximately 37 kDa. *CD79a* and *CD79b* share an exon-intron structure, which is similar to that of the genes that encode the CD3 TCR co-receptor molecules. These similarities suggest that both BCR and TCR co-receptors are the progeny of a common ancestral gene. Ig-α and Ig-β both contain a single IgSF Ig domain (111-residue C-type for Ig-α and 129-residue V-type for Ig-β). Each also contains a highly conserved transmembrane domain and a 61 (Ig-α) or 48 (Ig-β) amino acid cytoplasmic tail that also exhibits striking amino acid evolutionary conservation.

Ig-α and Ig-β are expressed by the earliest committed B-cell progenitors and before expression of Igμ heavy chain. The CD79 heterodimer has also been observed on the surface of early B-cell progenitors in the absence of μ heavy chain, although neither protein is required for progenitors to commit to the B-cell lineage.⁵⁰ Later in development, Ig-α and Ig-β are coexpressed together with Ig of all isotypes on the surface of B cells as a mature BCR complex.⁴⁸ The CD79 proteins are specific to the B lineage and are expressed throughout B lymphopoiesis. This has led to their use as markers for the identification of B-cell neoplasms.^{51, 52}

The signaling capacity of both Ig-α and Ig-β resides within an immunoreceptor tyrosine-based activation motif (ITAM) that has the consensus sequence of D/IxxYxxL(x)₇YxxL, where x is any amino acid. Similar ITAMs are also found within the cytoplasmic domain of the molecules that associate with, and signal for, the T-cell antigen receptor (CD3) and certain Fc receptors. The phosphorylation of both tyrosines in both Ig-α/β ITAMs is considered an obligate initial step in the propagation of an antigen receptor engagement event to the cell nucleus.^{49, 53} Tyrosine-phosphorylated ITAMs serve as efficient binding sites for Src homology 2 (SH-2) domains, which are present within a large number of cytosolic signaling molecules. Whether Ig-α and Ig-β make qualitatively different

Fig. 4.11 The B-cell receptor (BCR) core complex. The BCR core complex can be divided into an antigen recognition unit fulfilled by membrane immunoglobulin M (mIgM) and a noncovalently associated signal transduction unit composed of the Ig- α/β (CD79) heterodimer. Antigen engagement of mIgM oligomerizes the BCR, allowing preassociated Src-family protein tyrosine kinases to phosphorylate neighboring Ig- α/β ITAM tyrosines. This promotes association of the SYK tyrosine kinase with the tyrosine phosphorylated immunoreceptor tyrosine-based activation motif (ITAMs), allowing SYK to become a substrate for other Syk or Src-family tyrosine kinases and leading to its activation.

contributions towards BCR signaling or are functionally redundant remains unclear, as evidence exists to support both views. Moreover, the high degree of evolutionary conservation within the non-ITAM portion of the cytoplasmic domains suggests additional, as yet uncharacterized, signaling roles for the cytoplasmic tails of these molecules over and above positive signaling via the ITAMs.

Ig- α and Ig- β are covalently associated by a disulfide bridge via cysteine residues that exist within the IgSF extracellular domains of both molecules. The association of the Ig- α/β heterodimer with mIg occurs through interaction within the transmembrane domains of these proteins.⁴⁸ The core BCR complex consists of a single Ig molecule associated with a single Ig- α/β heterodimer (H₂L₂/Ig- α /Ig- β)⁵⁴ (Fig. 4.11).

A current model for the initiation of signals originating from the BCR (Fig. 4.11) proposes that antigens induce the clustering of BCR complexes, increasing their local density. The increase in density leads to the transfer of phosphate groups to the tyrosine residues of the Ig- α/β ITAM motifs.^{49, 53} Src-family tyrosine kinases, of which LYN, FYN, and BLK are most often implicated, are believed to be responsible for ITAM phosphorylation upon aggregation of Ig- α/β . They have been shown to associate physically with the heterodimer. It has been suggested that a fraction of Src-family tyrosine kinases is associated with

the Ig- α/β heterodimer and, upon aggregation, transphosphorylate juxtaposed heterodimers. However, the exact mechanism by which Ig- α/β undergoes initial tyrosine phosphorylation after antigen engagement remains uncertain. Regardless of mechanism, phosphorylated ITAMs subsequently serve as high-affinity docking sites for cytosolic effector molecules that harbor SH2 domains. The recruitment of the SYK tyrosine kinase, via its tandem SH2 domains, to doubly phosphorylated Ig- α/β ITAMs is thought to be a next step in propagating a BCR-mediated signal. Association of SYK with the BCR leads to its subsequent tyrosine phosphorylation by either Src-family or other Syk tyrosine kinases, further increasing kinase activity. Together, the concerted actions of the Syk and Src-family protein tyrosine kinases activate a variety of intracellular signaling pathways that can lead to the proliferation, differentiation, or death of the cell.⁵⁵

CLINICAL CONSEQUENCES OF DISRUPTIONS IN BCR SIGNALING

Both the development of B lymphocytes and the maintenance of the mature antigen-responsive B-cell pool demand the presence of an intact BCR and its downstream signaling pathway(s). Disruption of these pathways can present clinically with hypogammaglobulinemia and an absence of B cells.

The most common such genetic lesion is BTK deficiency, which is an X-linked trait (Chapter 34).⁵⁶ BTK plays an important role in BCR signaling both during development and in response to antigen. Loss of function mutations in *BTK* results in the arrest of human B-cell development at the pre-B-cell stage.

BTK is intact in approximately 10–15% of patients with hypogammaglobulinemia and an absence of B cells. Mouse models where BCR components or signaling pathways have been disrupted by targeted mutagenesis have provided insight into the basis of these atypical hypogammaglobulinemia disorders.⁴⁹ These studies have shown that an inability to express either a functional μ IgH chain, Ig- α , Ig- β , or the signaling adaptor molecule, BLNK, lead to an early, severe arrest in B lymphopoiesis, with subsequent agammaglobulinemia. Together, these experimental findings highlighted the central role of the BCR in the generation and function of B lymphocytes. They suggested that mutations in any component of the antigen receptor complex or immediate downstream effectors would have the potential to disrupt B-cell development and thus create an agammaglobulinemic state. These speculations were borne out when hypogammaglobulinemic individuals demonstrating an absence of B cells in the presence of normal BTK function were subsequently identified with mutations in either Ig μ heavy chain, Ig- α , or BLNK.⁵⁶

Besides its important role in the maturation, differentiation, and survival of B lymphocytes, the B-cell antigen receptor is responsible for initiating the humoral response to foreign antigen. Some of the variables that can influence the ultimate outcome of BCR-antigen interaction include the nature of the foreign antigen, the mode of activation, the developmental stage of the B cell, and the microenvironment in which antigen encounter occurs. Exactly how these variables ultimately result in the differential activation of diverse intracellular signaling pathways with fundamentally divergent outcomes is only beginning to be understood, and is an area of active investigation. Emerging from these studies is an appreciation of the role of BCR co-receptors, which have been shown to be capable of modulating antigen receptor signaling in response to antigen.

BCR CO-RECEPTORS

The initiation of a humoral immune response results from antigen interaction with the antigen receptors on mature peripheral lymphocytes. However, the manner in which mature B and T lymphocytes recognize antigen is fundamentally different (Chapter 6). Surface Ig, as a component of the BCR on B lymphocytes, recognizes antigen in its native three-dimensional configuration that, upon engagement with mIg, is capable of transmitting a signal to the cell interior. In contrast, the antigen receptor expressed by T lymphocytes recognizes an antigen-derived peptide associated with an appropriate MHC structure. Moreover, for a productive outcome of this T-cell recognition event, a CD4 or CD8 co-receptor must also bind to the MHC structure presenting the foreign antigen (Chapter 7). Similarly, antigen recognition by the BCR on B lymphocytes is also influenced by co-receptors present on mature B cells (Table 4.3). In this case the co-receptors may also recognize antigen, but only in a form that has been modified by other components of the immune system, as described below. In general, these co-receptors and co-receptor complexes can be divided into those that regulate BCR signaling in a positive manner and those that regulate in a negative manner. Thus, the ultimate outcome of signaling via the BCR depends not only on the signals transduced via the Ig- α/β heterodimer, but also how these signals are perceived by the cell in association with the signals propagated by the various co-receptors that are concomitantly engaged.

CO-RECEPTORS THAT POSITIVELY REGULATE BCR SIGNALING

CD21

Mature B lymphocytes express two receptors for complement C3 components, CD35 (CR1) and CD21 (CR2) (Chapter 20). Of these, CD21 fulfills the requirements of a BCR co-receptor, as described below. The expression of CD21 is restricted to mature B cells and follicular dendritic cells, whereas CD35 is also found on erythrocytes, monocytes, and granulocytes. CD21 is a 140-kDa surface glycoprotein encoded by the *CR2* locus on chromosome 1q32 (Table 4.3). Expression of CD21 begins at approximately the same time as IgD during B lymphopoiesis (Chapter 8). CD21 is subsequently expressed on all mature B cells until terminal differentiation. Within the mature population, marginal-zone B cells express higher levels relative to follicular B cells. The extracellular domain of CD21 is composed of 15–16 short consensus regions (SCRs), each composed of 60–70 amino acids, and a relatively short 34-amino-acid cytoplasmic tail. The two-amino-terminal SCRs constitute the region that interacts with one of the third complement component (C3) cleavage products, iC3b, C3d, g, and C3d (Chapter 20).⁵⁷

CD21 is a known receptor for Epstein–Barr virus, which similarly binds the two N-terminal SCRs via its major envelope glycoprotein gp350/220. CD21, through its oligosaccharide chains, also binds CD23, the low-affinity IgE receptor (Fc ϵ RII). Whereas Epstein–Barr virus utilization of CD21 for cell entry has clear physiological consequences in terms of infection, B-cell immortalization, and the potential for oncogenesis, the *in vivo* relevance of a CD21–CD23 interaction remains unclear.

CD19

CD19 is an IgSF surface glycoprotein of 95 kDa that is expressed from the earliest stages of B-cell development until plasma cell terminal differentiation, when its expression is lost.⁵⁸ Follicular dendritic cells also express CD19. *CD19* maps to chromosome 16p11.2, where it encodes for a 540-amino-acid protein with two extracellular C-type IgSF domains as well as a large, approximately 240-residue, cytoplasmic tail that exhibits extensive conservation between mouse and human. This relatively large cytoplasmic domain includes nine conserved tyrosine residues that, upon phosphorylation, serve as docking sites for other SH2-containing effector molecules. The signaling capacity of CD19 has been shown to result from tyrosine phosphorylation, which occurs upon engagement of the BCR, CD19 or, optimally, by co-ligation of CD19 and IgM. Known signaling effector molecules that have been identified in association with tyrosine-phosphorylated CD19 include the LYN and FYN protein tyrosine kinases, the Rho-family guanine nucleotide exchange factor, VAV, and phosphatidylinositol 3-kinase.⁵⁸ Although specific ligands for CD19 have been proposed, the physiological relevance of CD19 engagement by putative ligands has not been demonstrated.

In vitro studies using monoclonal antibodies directed against CD21 or CD19 provided initial evidence that these B-cell surface antigens could influence mIg-mediated signaling.^{57,58} Formal demonstration that these molecules played a physiological role in regulating B-cell responses was first provided by targeted mutagenesis in mouse models. CD21- and CD19-deficient mice demonstrate impaired antibody response to T-dependent antigens.^{57–59} The paucity of CD5⁺B cells in CD19-deficient mice also suggested a role for this molecule in the generation and maintenance of the B1 lineage of B cells (Chapter 8). CD19 is expressed from the earliest stages of B-cell ontogeny in both mice and humans and, accordingly, a signaling function for CD19 in B lymphopoiesis has been demonstrated.⁶⁰ CD19 deficiency has been shown to be a cause of common variable immune deficiency (Chapter 34).

CD21–CD19 co-receptor complex

A mechanism by which these molecules could augment BCR-mediated signaling was provided by the identification of a CD21/CD19 co-receptor complex on mature B cells that also includes CD81 (Fig. 4.12). CD81, also known as TAPA-1, is a 26-kDa tetraspan molecule that is widely expressed on a number of cell types, including lymphocytes. The CD21/CD19 co-receptor model predicted that, as a result of complement activation, C3d would be deposited on an antigen, thereby providing a bridge by which a CD21–CD19 receptor complex could associate with mIgM and the BCR complex.^{57–59} Clustering of CD19 close to the BCR by the C3d–antigen complex would effectively recruit the signal transduction effector molecules associated with CD19 to the Ig- α/β heterodimer. As a consequence, the CD19-associated LYN and FYN tyrosine kinases, VAV, and PI3-kinase signaling effector molecules would be in a position to exert their activities on the Ig- α/β heterodimer-mediated signaling events initiated by antigen engagement of mIgM.

Strong support for CD21/CD19 co-receptor physiological function in BCR signaling was subsequently provided by experiments using a murine model of immune response. In these experiments, the immunization of mice with an antigen covalently attached to C3d dramatically

Fig. 4.12 Proposed mechanisms for the augmentation of B-cell receptor (BCR) signaling by the CD21/19 co-receptor. Co-ligation of the BCR and CD21–CD19 complex by C3d–antigen complex allows a CD19-associated Src-family tyrosine kinase to phosphorylate tyrosine residues within the CD19 cytoplasmic domain. Subsequently, tyrosine-phosphorylated CD19 effectively recruits key SH2-containing signaling molecules to the BCR complex, allowing the initial BCR-mediated signal to disseminate quickly along different intracellular signaling pathways.

reduced the signaling threshold necessary for antigen to elicit an immune response.⁶¹ Antigen bearing either two or three copies of C3d was respectively 1000 and 10 000 times more immunogenic than antigen alone. Thus, the CD21–CD19 co-receptor complex provides a link between the innate and adaptive immune responses. *In vivo*, CD19-deficient mice appear to have more severely affected T-dependent immune responses than do CD21-deficient animals, suggesting alternative roles for CD19 in regulating BCR signals beyond the CD21/CD19 co-receptor complex.

CO-RECEPTORS THAT NEGATIVELY REGULATE BCR SIGNALING

FcγRIIB

Among the several receptors for the Fc portion of immunoglobulin expressed by B cells, the Fc receptor for IgG, FcγRIIB (a member of the CD32 cluster), has an important role in negatively regulating BCR-mediated signal transduction.⁶² FcγRIIB is a 40-kDa single-chain molecule that is encoded by a single gene located on chromosome 1q23–24. Alternative splicing of different cytoplasmic exons permits expression of three isoforms. The extracellular domain of FcγRIIB is composed of two C-type IgSF domains that can bind with low affinity to IgG. All three FcγRIIB isoforms share a common cytoplasmic region that is important for negatively regulating activation signals delivered by associated surface receptors. The region within the cytoplasmic domain of FcγRIIB

responsible for the inhibitory activity of this Fc receptor towards the BCR has been identified as a sequence that contains a tyrosine residue critical for its activity.⁶² In analogy to the ITAM, which provides an activation signal, this inhibitory sequence has been referred to as an immunoreceptor tyrosine-based inhibitory motif, or ITIM. The ITIM is carried by the canonical sequence of I/L/VxYxxI/V/L (where x is any amino acid).⁶³ ITIMs are found in a number of other transmembrane structures, all of which share the ability to regulate signaling negatively by activating receptors.

The ability of passively administered soluble antibody to inhibit humoral responses has long been appreciated and was initially thought to occur by soluble antibody, effectively masking all available antigen epitopes. The molecular mechanism accounting for this suppression is now known to be mediated by the binding of IgG to FcγRIIB and the subsequent recruitment of cytosolic phosphatases to the FcγRIIB ITIM upon tyrosine phosphorylation. Thus, the inhibitory effect of IgG on BCR-mediated B-cell activation is explained by the interaction of the FcγRIIB ITIM, and specifically associated phosphatases, with the BCR (Fig. 4.13). Co-ligation of the BCR and FcγRIIB by antigen–IgG complexes results in the tyrosine phosphorylation of the FcγRIIB ITIM, presumably by the BCR-associated tyrosine kinases. Phosphorylated FcγRIIB ITIMs then recruit two different SH2-containing phosphatases, SHIP and SHP-1, which function to remove phosphate groups from inositols or tyrosines, respectively. Although both phosphatases can negatively regulate BCR-mediated signaling events, SHIP appears to be the most relevant phosphatase in FcγRIIB inhibition of BCR signaling⁶⁴ (Fig. 4.13). Thus, once the majority of antigen exists in immune complexes together with antigen-specific IgG, attenuation of an ongoing immune response occurs by the juxtaposition of FcγRIIB with the BCR.

CD22

CD22 is a 135–140-kDa transmembrane glycoprotein that is restricted in its expression to the B lineage.⁶⁵ CD22 expression is limited to the cytoplasm of progenitor and pre-B cells in early B-cell development. Expression on the surface of the B cell occurs concomitant with the appearance of surface, or membrane, IgD. Upon B-cell activation, CD22 expression is initially transiently upregulated and subsequently downmodulated upon terminal differentiation to Ig-secreting plasma cells. Although the onset of CD22 expression follows a similar pattern during murine B lymphopoiesis, it is not restricted to the cytoplasm in early B lymphopoiesis but rather is expressed on the surface from the progenitor stage onward. The basis or function of CD22 intracellular retention in human B-cell development is not understood.

CD22 maps to chromosome 19q13.1 and encodes for alternatively spliced forms of CD22, CD22α and CD22β, of which the latter is the predominant species expressed by B cells. The CD22β isoform contains seven extracellular IgSF domains, of which all but one are of the C type. The single exception is the N-terminal domain, which is of the V type. CD22α lacks the IgSF third and fourth domains, although the significance of this minority alternatively spliced product remains unclear. The CD22 murine homolog has only been found as a full-length CD22β isoform. The extracellular domain of CD22 is homologous to the carcinoembryonic antigen subfamily of adhesion molecules, which includes the myelin-associated glycoprotein and CD33. CD22 also functions as an adhesion molecule belonging to the Siglec subfamily of the Ig superfamily, whose members function as mammalian sialic acid-binding Ig-like lectins.⁶⁵ The two amino-terminal IgSF domains have been shown

Fig. 4.13 Negative regulation of B-cell receptor (BCR) signaling by FcγRIIB and CD22. (A) Soluble immunoglobulin (Ig)G–antigen immune complexes juxtapose the BCR with FcγRIIB. The BCR-associated Lyn tyrosine kinase subsequently tyrosine phosphorylates the FcγRIIB ITIM. In turn, this leads to the recruitment of the SH2-containing inositol phosphatase SHIP and tyrosine phosphatase SHP-1 to the phosphorylated FcγRIIB ITIM. Both of these phosphatases have demonstrable inhibitory activity on BCR-mediated signaling. Although SHIP is believed to be the major effector in the FcγRIIB-mediated inhibition of BCR signaling,⁶⁴ the exact mechanism of its action in this context has not yet been fully elucidated. (B) CD22 associated with the BCR is tyrosine-phosphorylated upon antigen-BCR engagement. SH2-containing signaling molecules dock on tyrosine phosphorylated residues, including the SHP-1 tyrosine phosphatase that can subsequently dephosphorylate signaling molecules previously activated by a membrane immunoglobulin M (mIgM)-mediated signal.

KEY CONCEPTS

T-CELL RECEPTOR (TCR)–CD3 COMPLEX

- >> Cell surface expression of the TCR heterodimers requires association with a complex of invariant proteins designated CD3
- >> Each TCR–CD3 complex contains a single TCR heterodimer and three CD3 dimers
- >> Assembly of the TCR–CD3 complex involves interactions between TCR transmembrane basic residues and transmembrane acidic residues in each of the CD3 subunits
- >> Signal transduction by the TCR involves the phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) in the cytoplasmic domains of CD3 proteins:
 - >> Phosphorylated CD3 ITAMs recruit and activate the ZAP-70 protein tyrosine kinase
- >> Deficiency of CD3 proteins impairs T-cell development and can produce severe combined immunodeficiency (SCID)

to mediate adhesion to both B and T lymphocytes via the binding of structures carrying α2,6 sialic acids.

In addition to acting as an adhesion molecule, CD22 is also capable of modulating BCR signaling (Fig. 4.13). A fraction of CD22 associates with the BCR, and CD22 is rapidly tyrosine-phosphorylated upon mIgM engagement. Tyrosine-phosphorylated CD22 associates with several SH2-containing signaling molecules, including the LYN and SYK tyrosine kinases, PI3-kinase, phospholipase C-γ, and SHP-1. The 140-amino-acid cytoplasmic domain of CD22 includes six conserved tyrosine residues. Three of these tyrosines are located within conserved consensus ITIM sequences and possess a demonstrable capacity to bind the SH2 domain of the SHP-1 phosphatase. The presence of the multiple ITIMs and association with SHP-1 indicated that CD22 might impinge on BCR signaling in a negative manner. Physiological evidence that CD22 could act as a co-receptor to regulate mIgM signaling negatively was provided by the generation of CD22-deficient mice by targeted mutagenesis.⁶⁵ CD22-deficient B cells exhibited hyperactive B-cell responses upon BCR triggering, and an increased incidence of serum autoantibodies. This suggests that B-cell tolerance is altered and B cells are more readily activated in the absence of this negative regulator of BCR signaling.

THE TCR–CD3 COMPLEX

The αβ and γδ TCR heterodimers, which are responsible for the recognition of specific antigen by T lymphocytes, associate with a complex of invariant proteins designated CD3. This association is necessary for

Fig. 4.14 Schematic representation of the human T-cell receptor (TCR) and CD4 and CD8 co-receptors. Immunoglobulin superfamily (IgSF) domains are represented by ovals. The four extracellular domains of CD4 are labeled D1–D4. Basic (+) and acidic (–) transmembrane charged residues are indicated, as are known and predicted sites of disulfide bonds.

TCR cell surface expression and enables the TCR heterodimers, which have only short cytoplasmic domains, to couple to the intracellular signaling events that lead to the activation of T-cell effector function. There are four CD3 proteins: γ , δ , ϵ , and ζ (Fig. 4.14).⁶⁶

CD3 PROTEINS

CD3 γ , CD3 δ , and CD3 ϵ are structurally similar, and the genes encoding them map to a locus in chromosome 11q23. The polypeptides range in size from 20 to 25 kDa. Each has an extracellular C-type IgSF domain, a transmembrane region that contains an acidic residue (aspartic acid in CD3 δ and CD3 ϵ , glutamic acid in CD3 γ), and a cytoplasmic domain with a single ITAM. These CD3 chains are present in the TCR–CD3 complex in the form of noncovalently linked CD3 $\epsilon\gamma$ and CD3 $\epsilon\delta$ heterodimers.^{22, 66, 67}

The 16kDa CD3 ζ differs substantially from the other CD3 proteins and is structurally homologous to the γ chain of the high-affinity IgE receptor (FcR γ chain). The extracellular domain of CD3 ζ is very short (only nine amino acids) and is of unknown structure. Its large cytoplasmic domain has three ITAMs in tandem. As is the case with the other CD3 chains, the transmembrane region of CD3 ζ contains an acidic residue (aspartic acid). CD3 ζ is usually present in the TCR–CD3 complex in the form of disulfide-linked CD3 $\zeta\zeta$ homodimers.^{22, 66, 67}

STOICHIOMETRY OF THE TCR–CD3 COMPLEX

The valency and stoichiometry of the TCR–CD3 complex have been the subject of considerable interest and of some past controversy. Recent data indicate that the $\alpha\beta$ TCR–CD3 complex consists of a single $\alpha\beta$ TCR

heterodimer and three CD3 dimers: CD3 $\epsilon\gamma$, CD3 $\epsilon\delta$, and CD3 $\zeta\zeta$ (Fig. 4.14). The $\gamma\delta$ TCR–CD3 complex, in contrast, lacks CD3 δ . On naïve T cells, this receptor complex contains two CD3 $\epsilon\gamma$ heterodimers and one CD3 $\zeta\zeta$ homodimer. Following activation of $\gamma\delta$ T cells, the TCR–CD3 complex incorporates the FcR γ chain, either as a homodimer or as heterodimer with CD3 ζ .^{22, 67}

As noted above, each of the CD3 subunits has a transmembrane acidic residue while the transmembrane domains of the $\alpha\beta$ and $\gamma\delta$ TCRs contain basic residues. For example, the TCR α -chain has an arginine and a lysine within its transmembrane domain while the transmembrane region of the TCR β -chain contains a lysine. Because the receptor complex consists of one TCR heterodimer and three CD3 dimers, there is an apparent ‘charge imbalance’ with six acidic residues but only three basic residues.⁶⁷

ASSEMBLY AND CELL SURFACE EXPRESSION OF THE TCR–CD3 COMPLEX

Assembly begins with formation of the individual TCR $\alpha\beta$, CD3 $\epsilon\delta$, and CD3 $\epsilon\gamma$ heterodimers, processes that are driven by interactions between the extracellular domains of the pairing polypeptides. The subsequent higher-order assembly of the TCR $\alpha\beta$ with the CD3 dimers depends upon interactions between the potentially charged residues within their transmembrane regions. Mutation of any of these transmembrane acidic or basic residues to neutral alanine impairs formation of the TCR–CD3 complex. TCR $\alpha\beta$ appears to associate first with CD3 $\epsilon\delta$ and then with CD3 $\epsilon\gamma$. TCR α binds CD3 $\epsilon\delta$, and TCR β likely interacts with CD3 $\epsilon\gamma$. The incorporation of a CD3 $\zeta\zeta$ homodimer into the complex requires the prior formation of a TCR $\alpha\beta$ –CD3 $\gamma\epsilon$ –CD3 $\delta\epsilon$ hexamer.

The structure of transmembrane region of TCR α is not known. If, as seems likely, this region has an α -helical structure, then the two transmembrane basic residues would lie on opposite faces of the helix, possibly allowing TCR α to interact with CD3 ζ as well as CD3 $\epsilon\delta$.

Formation of the TCR-CD3 complex is tightly regulated. For example, when there are deficiencies of CD3 γ , CD3 δ , or CD3 ϵ , TCR α and β are retained in the endoplasmic reticulum and are rapidly degraded. In the absence of CD3 ζ , the TCR $\alpha\beta$ -CD3 $\epsilon\gamma$ -CD3 $\epsilon\delta$ hexamer is exported to the Golgi but is then targeted to a lysosomal degradation pathway rather than the cell surface.^{22, 66, 67}

Because the structures of most of the individual components of the TCR-CD3 complex are known, a model of the overall structure of the receptor has been proposed. This model envisions a compact TCR-CD3, with trimeric contacts occurring within the transmembrane regions of all components (i.e., TCR α -CD3 ϵ -CD3 δ , TCR β -CD3 ϵ -CD3 γ , and TCR α -CD3 ζ -CD3 ζ) and with the TCR $\alpha\beta$ extending further from the membrane than the CD3 chains.^{22, 68}

Mutations in the *CD3D*, *CD3E*, *CD3G*, and *CD3Z* have been described in human. The clinical consequences of these mutations underscore the importance of the CD3 proteins for the normal development and function of T cells. Homozygous mutations leading to complete deficiencies of either CD3 δ or CD3 ϵ protein produce a form of SCID (Chapter 35) characterized by the complete absence of T cells but the presence of phenotypically normal B cells and natural killer (NK) cells (T-B⁺NK⁺SCID).^{69–71}

The absence of CD3 ϵ leads to a complete block early in T-cell development, which, in CD3 ϵ -knockout mice, occurs at the CD4⁺CD8[−] “double-negative” stage (Chapter 9).

Homozygous deficiency of CD3 δ produces a block at a slightly later stage in T-cell development, at the entry of thymocytes into the CD4⁺CD8⁺ “double-positive” stage.

Interestingly, deficiency of CD3 γ produces a milder phenotype than does the absence of either CD3 δ or CD3 ϵ . Homozygous deficiency in CD3 γ has been observed in two brothers but, surprisingly, manifested clinically as severe immunodeficiency and autoimmunity in only one of these.⁷¹ The second brother survived to adulthood with only mild autoimmunity. The absence of CD3 γ protein impaired, but did not abrogate, T-cell development. In peripheral blood, there were differential effects on phenotypically defined T-cell subsets, with very few CD8⁺T cells, a 10-fold reduction in CD4⁺CD45RA⁺T cells (“naïve helper” subset), and normal numbers of CD4⁺CD45RO⁺T cells (“memory” cells). Cell surface expression of the TCR-CD3 complex on peripheral T cells was reduced by 75–80%.⁷¹

There have been no reports of individuals homozygous for null mutations of *CD3Z*. However, a point mutation leading to a premature stop codon within the first ITAM of CD3 ζ has been identified. An individual homozygous for this *CD3Z* mutation presented with severe immunodeficiency at age 4 months. Peripheral blood CD4 and CD8 T cells were reduced in number, expressed low levels of cell surface TCR-CD3 complex, and were hyporesponsive to TCR stimulation *ex vivo*.⁷²

EARLY EVENTS IN TCR-CD3 SIGNALING

Stimulation of the TCR-CD3 complex by pMHC, or by nonphysiological agonists such as anti-CD3 monoclonal antibodies, leads to the phosphorylation of tyrosine residues of the CD3 ITAMs by the

SRC-like protein tyrosine kinases, LCK and FYN.⁷³ The phosphorylated CD3 ITAMs in turn create high-affinity binding sites for the SH2 domains of the ZAP-70 protein tyrosine kinase, leading to its recruitment to the TCR-CD3 complex and to its activation (Chapter 13).^{73, 74} The consequences of ZAP-70 deficiency (selective T-cell immunodeficiency in humans) underscore the centrality of its role in T-cell activation (Chapter 35).

It is not known how the binding of pMHC to the TCR transfers information through the receptor complex, thereby triggering the cascade of complex biochemical events leading to the activation of T-cell effector function. A number of possible models have been proposed to explain the initiation of TCR-CD3 signaling by pMHC. In one set of scenarios, a pMHC-induced conformational change in the TCR causes the TCR heterodimer to change its orientation with respect to the CD3 dimers. In another, the entire TCR-CD3 complex acts as a rigid structure, and pMHC binding leads to displacement of the CD3 chains into the membrane or alters their orientation with respect to the membrane. Following the initiation of signaling, sustained signaling appears to involve multimerization of TCR-CD3 complexes and engagement of co-receptors.⁶⁶

T-CELL CO-RECEPTORS: CD4 AND CD8

Expression of CD4 and CD8 divides mature T cells into two distinct subsets: CD4 T cells (Chapter 17), which recognize peptides in the context of class II MHC molecules, and CD8 T cells (Chapter 18), which recognize antigens presented by class I MHC molecules. Indeed, CD4 binds directly to class II MHC molecules, and CD8 interacts directly with class I MHC molecules (Fig. 4.15); in both cases binding involves nonpolymorphic regions at the base of the MHC molecule (Chapter 5). During antigen recognition, CD4 and CD8 are thought to bind the same pMHC complex as the TCR and thus are true co-receptors for the TCR. The cytoplasmic domains of CD4 and CD8 associate with LCK, and, in current models of TCR signaling, these co-receptors bring LCK into contact with the CD3 chains of the pMHC-engaged TCR-CD3 complexes and thus play an important role in the phosphorylation of CD3 ITAMs (Chapter 13). The CD4 and CD8 co-receptors are needed for full T-cell activation.^{73, 75–77}

The expression of the CD4 and CD8 co-receptors is highly regulated during T-cell development in the thymus. Thymocytes initially express neither co-receptor (“double-negative”). CD4⁺CD8[−] thymocytes destined to become TCR $\alpha\beta$ T cells progress through a CD4⁺CD8⁺ (“double-positive”) stage to become mature CD4⁺CD8[−] or CD4⁺CD8⁺T cells. Positive and negative selection of thymocytes on the basis of their TCR specificities and commitment to the CD4 or CD8 lineages occur during the double-positive stage (Chapter 9).

CD4: STRUCTURE AND BINDING TO MHC CLASS II MOLECULES

A member of the immunoglobulin superfamily, CD4 is a 55-kDa glycoprotein that can be expressed either as a monomer or a dimer on the cell surface. Its relatively rigid extracellular region contains four IgSF domains (designated D1–4). The cytoplasmic domain of CD4 contains two cysteine residues that mediate its noncovalent interaction with

Fig. 4.15 Illustration of the interactions between the T-cell receptor (TCR), peptide–major histocompatibility complex (pMHC), and CD8. A composite illustration of the human leukocyte antigen (HLA)-A*0201 structure in complex with a Tax peptide and its cognate TCR α - and β -chains (protein databank (pdb) designation 1BD2) with the human CD8 α /HLA-A*0201 structure (pdb designation 1AKJ) was generated by superposition of the HLA moiety of the two structures. The HLA heavy chain is indicated as MHC, its light chain (β_2 -microglobulin) as β_2 -m, the CD8 α homodimer as CD8, the TCR α - and β -chains as TCR α and TCR β . In addition, the CD4 homodimer (pdb file 1WIO) is shown to scale. Connecting peptides, transmembrane, and cytoplasmic domains are drawn by hand and indicated by dotted lines. Courtesy of David H. Margulies, National Institute of Allergy and Infectious Diseases, National Institutes of Health.

LCK through a ‘zinc clasp’-like structure formed with a dicysteine motif in the N-terminal region of LCK.^{73, 75, 76}

The crystal structure of the CD4 D1D2 fragment bound to pMHC class II demonstrates that the N-terminal domain (D1) of CD4 binds between the membrane-proximal α_2 and β_2 domains of MHC class II. Thus CD4 interacts with pMHC class II at a distance from the α -helices and peptide contacted by the TCR. This enables the TCR and CD4 to bind the same MHC class II molecule simultaneously. Models for the structure of TCR $\alpha\beta$ –pMHC–CD4 indicate that this ternary complex assumes a V-shape with pMHC at the apex and with TCR $\alpha\beta$ and CD4 forming the arms of the V. In this model, therefore, there is no direct interaction between the co-receptor and the TCR heterodimer, suggesting that pMHC brings the TCR and CD4 together. The model does not address the localization of the CD3 dimers, but raises the possibility that the CD3 chains lie within the open angle between TCR $\alpha\beta$ and CD4, promoting interactions between CD3 chains and CD4-associated LCK.^{73, 75, 76}

Experiments using soluble forms of CD4 and pMHC reveal that monomeric CD4 binds pMHC with very low affinity (K_d approximately 200 μ M). The binding of CD4 to pMHC is of lower affinity than that TCR $\alpha\beta$ to pMHC (K_d 1–10 μ M) and displays more rapid kinetics. Because of the low affinity and the rapid off-time, it is unlikely that interactions of CD4 with MHC class II molecules initiate the interaction between a T cell and an antigen-presenting cell. Rather,

these binding characteristics are more compatible with a model in which the initial event is the interaction between the TCR and pMHC, followed by the recruitment of CD4, which then stabilizes the interaction and promotes signaling events.^{73, 75–77}

CD8: STRUCTURE AND BINDING TO MHC CLASS I MOLECULES

There are two CD8 polypeptides, α and β , and these are expressed on the cell surface either as a disulfide-linked CD8 $\alpha\alpha$ homodimer or as a disulfide-linked CD8 $\alpha\beta$ heterodimer. On most $\alpha\beta$ T cells, CD8 $\alpha\beta$ is the predominant form of CD8. However, NK cells (Chapter 18) and $\gamma\delta$ T cells exclusively express CD8 $\alpha\alpha$.^{73, 75, 76}

CD8 α , a 34–37-kDa protein, and CD8 β , a 32-kDa protein, share about 20% amino acid sequence homology. Both are glycoproteins and IgSF members. Although CD8 subserves a co-receptor function similar to that CD4, in structure it differs substantially from CD4. The CD8 extracellular regions have single N-terminal IgSF V domains at the end of extended mucin-like stalk regions of 48 amino acids (CD8 α) or 35–38 amino acids (CD8 β). A striking difference between the two forms of CD8 lies within the cytoplasmic domain. CD8 α , like CD4, contains a cysteine-based motif that enables it to interact with LCK through a ‘zinc clasp’-like structure. In contrast, CD8 β lacks this

Table 4.4 CD28 superfamily

Receptor	Expression	Ligand	Function on T cells
CD28	Most CD4 T cells 50% CD8 T cells	B7-1 (CD80) B7-2 (CD86)	Co-stimulation of IL-2 production and proliferation; promote T-cell survival
ICOS	Activated and memory T cells NK cells Not expressed by naïve T cells	ICOS ligand	Differentiation and effector T-cell function
CTLA-4	Upregulated after T-cell activation	B7-1 (CD80) B7-2 (CD86)	Inhibits IL-2 production and proliferation Promotes peripheral T-cell tolerance
PD-1	Upregulated after activation of T and B cells, myeloid cells	PD-L1 (B7-H1) PD-L2 (B7-DC)	Inhibits proliferations and cytokine production
BTLA	T and B cells, myeloid cells, dendritic cells	HVEM (herpes virus-entry mediator)	Inhibits T-cell proliferation

IL-2, interleukin-2; NK, natural killer.

motif and does not associate with LCK. Interestingly, CD8 $\alpha\beta$ appears to be a more effective activator of TCR signaling than CD8 $\alpha\alpha$. This may reflect the palmitoylation of the cytoplasmic domain of CD8 β , which allows CD8 $\alpha\beta$ to associate with lipid rafts during T-cell activation.^{73, 75, 76, 78}

The structure of CD8 $\alpha\alpha$ -pMHC class I complexes demonstrates that CD8 $\alpha\alpha$ attaches primarily to the α_3 domain of MHC class I (i.e., a nonpolymorphic, membrane-proximal region of the molecule distinct from the peptide-binding groove engaged by the TCR) (Chapter 5). Compared to the interaction of CD4 and MHC class II, binding is more antibody-like, with a loop of the MHC α_3 domain locked between the CDR-like loops of the two CD8 α IgSF V domains. Models of the structure of the TCR $\alpha\beta$ -pMHC-CD8 ternary complex propose a V shape similar to that of the model for TCR $\alpha\beta$ -pMHC-CD4, with pMHC at the apex of the V and the TCR and CD8 forming the arms of the V. CD8 binds to pMHC with lower affinity and with faster kinetics than the TCR. Thus, the binding properties of the CD8 co-receptor, like those of CD4, are consistent with a model in which the TCR initiates pMHC binding, followed by engagement of CD8 to the same pMHC.^{73, 75–78}

CO-STIMULATORY AND INHIBITORY T-CELL MOLECULES: THE CD28 FAMILY

Although the T-cell response to antigen requires the binding of the TCR and its co-receptors to pMHC, additional receptor–ligand interactions can affect the outcome by delivering signals that promote activation (co-stimulation) or that inhibit it (Table 4.4). Prominent among these are the interactions of members of the CD28 family with their cell surface ligands on antigen-presenting cells. This family includes CD28, inducible costimulator (ICOS), cytotoxic T-lymphocyte-associated

antigen-4 (CTLA-4), B- and T-lymphocyte attenuator (BTLA), and program death-1 (PD-1). CD28 and ICOS are co-stimulatory receptors; the major functions of CTLA-4, PD-1, and BTLA are inhibitory. CD28 and CTLA-4 are T-cell-specific whereas BTLA and PD-1 are also expressed by B cells and ICOS by NK cells.^{79–81}

All members of the CD28 family have a single extracellular IgSF V domain and have, as their ligands, members of the B7 family of cell surface molecules. CD28, CTLA-4, and ICOS are expressed on the cell surface as disulfide-linked homodimers. Their cytoplasmic domains contain the SH2-binding motif YXXM. In contrast, PD-1 and BTLA are monomers whose cytoplasmic domains each contain an ITIM and an immunoreceptor tyrosine-based switch motif (ITSM).

The best-characterized members of the CD28 family are CD28 and CTLA-4. CD28 is the prototypic co-stimulatory receptor. Virtually all human CD4 T cells constitutively express CD28, as do half of the CD8 T cells. CD28 stimulation usually does not elicit a cellular response in the absence of TCR signaling. However, CD28 signals can act in concert with TCR signals to promote cytokine production, T-cell expansion, and T-cell survival. TCR signaling in the absence of CD28 co-stimulation can induce T-cell anergy (Chapter 13).

CTLA-4 inhibits the response to TCR and CD28 signals and acts to terminate T-cell responses. T-cell activation induces CTLA-4, whose cell surface expression is tightly regulated by the cytoplasmic motif YVKM. In the unphosphorylated state, this motif binds to AP-1 and AP-2 clathrin adaptor complexes that target CTLA-4 to intracellular compartments. Phosphorylation of the tyrosine releases the adaptor complexes and increases cell surface expression of CTLA-4.^{79, 80}

CD28 and CTLA-4 bind to the same ligands, B7.1 (CD80) and B7.2 (CD86), and interact with these B7 ligands through a conserved hydrophobic MYPPPY motif in their extracellular domains. Nonetheless, CD28 and CTLA-4 differ in the valency of binding. CD28 is monovalent whereas CTLA-4 binds two B7 ligands. And the affinity of CTLA-4 for B7.1 and B7.2 is substantially greater than that of CD28.⁸¹ Thus, the inhibitory complexes formed by CTLA-4, particularly those

involving B7.1, are more stable than the co-stimulatory interactions involving CD28.

Inhibition of T-cell activation by CTLA-4 appears to involve competition for B7 ligands and the generation of intracellular signals. In addition, CTLA-4 may induce 'reverse signaling' through B7.1 and B7.2 to the antigen-presenting cell, leading to the upregulation of the enzyme indoleamine 2,3-dioxygenase (IDO), which in turn breaks down tryptophan, a requirement for T-cell proliferation.⁸²

The importance of CD28 co-stimulation has made it an attractive target for therapeutic intervention. Indeed, abatacept, a soluble fusion protein composed of the extracellular domain of human CTLA-4 and the constant regions of human IgG₁, is an effective therapy for the treatment of rheumatoid arthritis (Chapter 52). Abatacept is thought to inhibit CD28 co-stimulation through blockade of its B7 ligands, but some of its immunosuppressive effects may be indirect through the induction of IDO and consequent local depletion of tryptophan.⁸³

The major histocompatibility complex

Robert J. Winchester

5

The term *major histocompatibility complex* (MHC) refers to the first biologic role identified for the polymorphic classical MHC molecules encoded in this region of the genome, that of governing transplant rejection. Growing appreciation of the role of MHC-encoded molecules in binding processed antigens for recognition by T cells has made it clear that MHC genes are centrally involved in regulating the adaptive immune response and determining susceptibility to many autoimmune diseases.¹ In the human the classical MHC genes are alternatively termed *human leukocyte antigen* (HLA) genes and the MHC itself is sometimes termed the *HLA region*.

Among the key aspects of the functional biology of classical MHC genes are their central function in the recognition of processed antigen by T cells, the biologic role their polymorphism plays in this recognition, and the importance of block inheritance of sets of polymorphic MHC genes encoded by different loci. In this chapter we will explore the significance of these aspects, examine the function of the various major MHC genes, and explore the implications of their polymorphisms.

■ CLASSICAL MHC MOLECULES DETERMINE HOW T CELLS RECOGNIZE PROCESSED ANTIGEN ■

T cells recognize a subset of the amino acid side chains of peptides derived from processed proteins. These peptides, which average nine amino acids in length, are anchored to pockets on the surface of classical MHC

molecules by at least two of their amino acid side chains. The T cell recognizes a complex ligand composed of both the bound peptide and the presenting MHC, or *p-MHC*. Although the mode of TCR docking on MHC molecules is globally conserved, the shapes and chemical properties of the interacting surfaces found in these complexes are so diverse that no fixed pattern of contact has been recognized even between conserved TCR residues and conserved side chains of the MHC α -helices.²

In the adaptive immune response, the p-MHC ligand functions by presenting nonself peptide to T cells in the context of self-MHC. However, p-MHC are also the elements that select the repertoires of

KEY CONCEPTS

FUNCTIONAL BIOLOGY OF CLASSICAL MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) GENES

- >> T-cell recognition of processed peptides depends on the property of MHC molecules to bind small peptides
- >> Self-peptide-MHC complexes select the T-cell repertoire in the thymus
- >> Nonself-peptide-MHC complexes are recognized by T cells during an adaptive immune response
- >> MHC class I and II MHC genes are extremely *polymorphic*. Each allele at each human leukocyte antigen (HLA) locus encodes molecules with different peptide-binding properties that influence the particular peptides recognized by the T cells and thereby regulate the adaptive immune response
- >> Polymorphism is maintained by *frequency-dependent selection*, where the fitness of an individual bearing a common allele decreases because certain pathogens can adapt to the particular common structure and infect them more efficiently
- >> The *immunologic self* is the set of self-peptides and self-MHC molecules that select the TCR repertoire and which constitute the T-cell recognition component of an individual's adaptive immune system

CLINICAL RELEVANCE

- >> Major histocompatibility complex (MHC) class I molecules play a key role in governing transplant rejection
- >> The MHC class I and class II genes are the major genetic determinants of susceptibility to a number of autoimmune diseases due to the role of self-peptide and self-MHC in defining the recognition features of the T-cell arm of the adaptive immune system

T-cell clones generated during the thymic clonal selection process, as well as those that maintain the repertoire of naïve T cells (Chapter 9). Thus, in these instances self-peptide MHC complexes are surrogates for nonself peptides.³ *Immunologic self* is the set of self-peptides and self-MHC molecules that select the TCR repertoire and which constitute the T-cell recognition component of an individual's adaptive immune system.

Basically the T-cell immune system protects the body from two major types of pathogens, viruses that commandeer the replicative machinery of a cell and bacteria that replicate autonomously and often extracellularly. The two specialized forms of MHC class I and class II molecules influence the recognition and response of the adaptive immune system to peptides derived from these two broad classes of pathogens in contrasting ways. To terminate viral infection, a cell harboring virus is killed by a cytotoxic CD8 T cell that recognizes viral peptides bound to the MHC class I molecules. In contrast a typical bacterium is eliminated by being phagocytized by a macrophage or neutrophil. The CD4 T cell recognizes the peptides of this bacterium bound to MHC class II molecules and directs the adaptive immune system either to locally activate the macrophage to a heightened state of antibacterial activity or to foster production of specific antibodies that opsonize the bacterium. The critical difference between killing or helping the antigen-presenting cell depends on whether class I or class II MHC molecules are loaded with pathogen peptide. Both the differential lineage expression of class I versus class II and the way pathogen peptides are loaded on the two classes of MHC molecules direct the recognition process.⁴ The CD4 and CD8 co-receptors (Chapters 4 and 7) that interact with the class II and class I molecules respectively also appear to play an important role in this recognition process.²

Duplication of MHC genes involved in peptide presentation is a genetic strategy that offers additional varieties of peptide-presenting structures, which enhance the variety of presented peptides.⁵ There are three types of classical MHC class I molecules, HLA-A, HLA-B, and HLA-C, and three types of MHC class II molecules, HLA-DR, HLA-DQ, and HLA-DP.⁶ Each type of MHC molecule in an individual selects its own repertoire of T cells that are restricted in their ability to react only to peptides presented in the context of the same type of MHC molecule.

Virally encoded genes can decrease the expression of the class I MHC surveillance system through which they are identified.⁷ This attempt to escape surveillance is countered by the extensive interaction of class I molecules with various natural killer (NK) receptors. These interactions provide a mechanism for detecting decreases in MHC class I expression, which is termed recognition of *missing self*.⁸

BIOLOGY OF MHC POLYMORPHISM

Since a given MHC molecule specifically binds particular amino acid side chains of the peptide, only a relatively few peptides from any protein are likely to bind to a given type of MHC molecule, restricting T-cell recognition. This shortcoming is compensated at the species level by the *polymorphic* nature of the MHC class I and II MHC genes. Nearly all of the polymorphic changes distinguishing individual alleles at each HLA locus encode molecules with different peptide-binding properties. This allows the individual members of a species to recognize different portions of a given protein molecule in their T-cell immune response in a manner

dependent on the binding properties of their particular HLA allotypes. This restriction constrains their T-cell repertoire to recognizing different MHC-dependent immunodominant T-cell epitopes. The three maternally and three paternally derived class I alleles of HLA-A, HLA-B, and HLA-C are codominantly expressed to create six different antigen-binding structures that are each recognized by T cells from the six separate T-cell repertoires.

A *genetic polymorphism* implies that alleles of a gene are present at a frequency greater than expected from random mutation due to selection for diversity. In the case of the HLA genes, there is no preponderant wild-type allele. Multiple MHC polymorphisms provide a major evolutionary survival benefit, since they equip the species with a large number of very specific, but alternative, MHC molecules that differ in their binding pockets and present different peptides.¹ This prevents the creation of shared antigen recognition structures that a pathogen could readily counter by means of mutation. The existence of multiple HLA alleles with no dominant wild-type allele all maintained at stable levels is an example of *balancing selection*. The most likely responsible factor driving this equilibrium is *frequency-dependent selection*, where the fitness of an individual bearing a common allele decreases because certain pathogens can adapt to the particular common structure and more efficiently infect those bearing a common MHC peptide-binding structure. The remarkably different frequency of the HLA alleles in different ethnic subsets tells the history of the successful adaptation of our ancestors' adaptive immune systems to a new environment with different pathogens, as well as bottlenecks resulting from migration and perhaps survival during periods of massive epidemics.

MHC polymorphisms have clinical consequences. The large number of different HLA alleles greatly reduces the probability that two unrelated individuals will inherit an identical set of MHC genes, making the immunologic self close to unique for each unrelated individual. The phenomenon of near-universal rejection of transplants between unrelated individuals is a reflection of this, because one person's T-cell repertoire will typically recognize another individual's self-peptide:MHC molecules as equivalent to a pathogen peptide:MHC interaction. Conversely, because the T-cell portion of the adaptive immune system is entirely selected on self-peptide presented by self-MHC allotypes in the thymus, should education of clones to respond only to nonself pathogen peptides fail, the inherent autoreactivity of the T-cell system will set the stage for the development of autoimmune diseases that are associated with the recognition of particular self-peptides which are ably presented by self MHC. This accounts for the association of certain HLA alleles with disease susceptibility.⁹

The MHC genes are organized into regions that perform different functions, but are inherited together in large blocks. The short arm of chromosome 6 (6p22.2-p21.3) contains the 3.6 million bases of the MHC. Of the 128 expressed genes in the MHC, over 50 appear likely to have an immune function. According to the distribution of the HLA genes, the MHC is subdivided into two principal regions (Fig. 5.1). The class I region is found at the telomeric end of the locus. This region, which contains the HLA-A, -B, and -C genes, as well as other class I gene family members, is principally concerned with CD8 T-cell peptide recognition and NK cell recognition. The class II region is located at the centromeric end of the locus. This region, which contains the genes encoding HLA-DR, -DQ, and -DP and other

81 ■

surveillance mechanism for missing self. Class Ib MHC molecules engage NK receptors (NKR) such as heterodimeric CD94/NKG2A or CD94/NKG2C encoded by the killer cell lectin-like receptor family at 12p12-13 and expressed on NK cells, effector CD8 T cells, and the cytotoxic subset of CD4 T cells¹¹(Chapter 18).

The class I region also includes stress-induced MICA and MICB (MHC class I polypeptide-related sequence A and B) that are distantly related members of the class I family.⁵ They are similar to MHC class I molecule α -chains, but do not associate with β_2 -microglobulin or bind peptides. They encode heavily glycosylated proteins that are ligands for the activating NKG2D receptor (KLRK1), another member of the killer cell lectin-like receptor complex.¹² Binding of the MICA/B ligand to NKG2D on NK cells, CD8 $\alpha\beta$ T cells, and $\gamma\delta$ T cells activates their

cytolytic response. These pathways involving NKR engagement are important in a number of inflammatory responses, e.g., they account for much of the injury of the intestinal epithelium in celiac disease.¹³

Half of the expressed genes in the class I region have no apparent function in the immune system, including some ancient genes that antedate the development of the adaptive immune system. The organization of the class I region is distinctly different between rodents and humans. The different class I genes in each of the two species evolved from different groups of ancestral class I genes, thus rodent and human class Ia genes are not considered *orthologues*.

CLASS I MOLECULE

The genetically polymorphic 44 kDa α -chain of the HLA-A, HLA-B, or HLA-C molecule is 362–366 amino acids long and consists of five domains. The \sim 30 amino acid C-terminal cytoplasmic domain is connected to a \sim 25-amino-acid transmembrane domain. The extracellular portion of the molecule consists of a \sim 90-amino-acid supporting stalk, the α_3 domain, and the similarly sized α_1 and α_2 domains that together form the peptide-binding portion of the molecule and the surface that interacts with the TCR or NKR (Fig. 5.2). The exon–intron organization of the class I gene parallels the domain organization, with exon 1 encoding the leader, exons 2–4 α_1 –3, exon 5 the transmembrane region, and exons 6 and 7 the cytoplasmic region.

The ends of the class I peptide-binding cleft are closed and fix the peptide's orientation to facilitate TCR recognition. The sides of the peptide-binding cleft are composed of α -helices and the floor is composed of asymmetric strands of β -pleated sheet. Typically, two amino acid side chains of the peptide bind to pockets formed into the side and base of the groove. Consistent with their surveillance role for viral infections, classical class I molecules are expressed on nearly all nucleated cells. The expression of class I molecules is upregulated by α , β , and γ -interferons, granulocyte–macrophage colony-stimulating factor, and certain other cytokines. Expression is governed by the class I regulatory element located \sim 160 nt upstream from the initiation site which binds a number of regulatory factors, including those induced by interferons.

During their synthesis MHC class I molecules are loaded with antigenic peptides in three steps (Chapter 6). First, following ubiquitylation,

KEY CONCEPTS

CLASS I MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) GENES

- >> The class I region contains the polymorphic human leukocyte antigen (HLA)-A, -B, and -C genes and the less polymorphic, nonclassical class Ib genes, HLA-E, HLA-F, and HLA-G genes
- >> HLA-A, -B, and -C molecules are expressed on the surface of virtually all nucleated cells
- >> HLA-A, -B, and -C are loaded with antigenic peptides derived from cytoplasmic proteins following their cleavage in the proteasome complex and present these peptides, both self and nonself, to clonal peptide-specific T-cell receptors (TCR) of CD8 T cells
- >> Each MHC allotype selects its own T-cell repertoire. Thus there are usually six different repertoires in a person's CD8 T-cell population, each specialized for a maternally or paternally derived HLA-A, -B, and -C allotype
- >> Class Ib molecules contain a very limited variety of self-peptides and engage lectin family natural killer receptors (NKR) in the recognition of *missing self*

Table 5.1 Contrast of classical and nonclassical major histocompatibility complex (MHC) class I and II molecules

MHC class	Ia	Ib	IIa	IIb
Polymorphism	High	Low	High	Low
Distribution	All nucleated cells	Restricted	Professional antigen-presenting cells	Restricted, endosome
Loci	HLA-A, B, C	HLA-E, G	HLA-DR, DQ, DP	HLA-DM, DO
Receptors	TCR $\alpha\beta$, $\gamma\delta$	CD94/NKG2A,C	TCR $\alpha\beta$	None, chaperone function
Presents	Many cytoplasmically self- and nonself-derived peptides	Few peptides, e.g., class Ia leader	Peptides from ingested proteins and self-peptides	HLA-DR, DQ, DP

HLA, human leukocyte antigen; TCR, T-cell receptor.

cytoplasmic proteins are targeted to the proteasome complex that cleaves them at basic and hydrophobic residues, yielding peptides suitable for binding to class I MHC.¹⁴ Second, the peptides are actively translocated across the endoplasmic reticulum membrane by the selective TAP-1 and TAP-2 transporters that preferentially process peptides of 8–13 amino acids in length. Third, with the aid of chaperone proteins such as calnexin, calreticulin, and tapasin, the peptides are placed in the assembling MHC class I heterodimers. Some components of this system are encoded in the class II region (Fig. 5.1).

Analogous to the interaction of class Ib molecules with NKR, HLA-A, -B, or -C molecules are also ligands for a different group of NKR, the killer inhibitor receptors (KIR).^{11, 15} Whether or not the molecules engage the inhibitory KIR3DL1 and thereby influence the potential for NK inhibition is determined by amino acid polymorphisms in the C-terminus of the α -helix around position 80. These polymorphisms allow subdivision of HLA-B alleles into two subclasses, designated HLA-Bw4 and HLA-Bw6.

Fig. 5.2 The three-dimensional structure of human leukocyte antigen (HLA)-B27. The α -helical margins of the peptide-binding cleft contain the bound peptide RRIKAITLK, which is oriented with its amino-terminus to the left. There are extensive contacts at the ends of the cleft between peptide main-chain atoms and conserved MHC side chains, with the peptide amino and carboxyl termini tethered by H bonds and charge interactions. The peptide reciprocally stabilizes the three-dimensional fold of HLA-B27. The side chain of arginine in the P2 position of the peptide inserts into the B pocket, which contains an oppositely charged glutamic acid at its base. The resulting salt bridge is the dominant anchor for the peptide. Side chains P4, P6, and P8 make minor contributions to the interaction of the peptide with the HLA-B27 molecule. The central region of the peptide is left free to interact with a TCR. (Modified from Madden DR, Gorga JC, Strominger JL et al. The three-dimensional structure of HLA-B27 at 2.1 Å resolution suggests a general mechanism for tight peptide binding to MHC. Cell 1992, 70: 1035, with permission from Elsevier.)

The HLA-C alleles are also subdivided according to the amino acid encoded at position 80 into C1, where the amino acid is asparagine, and C2, where the amino acid is lysine. The C1 subset of HLA-C molecules can serve as ligands for KIR2L2 and KIR2DL3, while the C2 subset interacts specifically and more strongly with KIR2DL1. The presence of the lysine at position 80 of HLA-C and the corresponding KIR receptors are features unique to humans and chimpanzees.¹⁵

The HLA-C–KIR interaction plays a major role in the tolerance of the fetal allograft. Tolerance of the paternally inherited MHC molecules of the fetus encoded by fetal allograft involves a number of mechanisms. The fetally derived trophoblast containing the paternal HLA genes does not express HLA-B and HLA-A, but expresses HLA-C along with the nonclassical MHC class Ib molecules HLA-G and HLA-E. *Pre-eclampsia* occurs in 2–10% of pregnancies. The highest risk for pre-eclampsia is in mothers who inherit two C2 HLA-C alleles and KIR haplotypes encoding KIR2DL1, a combination capable of giving the greatest inhibitory signal to the many NK cells in the placenta. This inhibition appears responsible for the underlying defect in pre-eclampsia – the failure of placental trophoblast to invade maternal arterioles sufficiently to achieve adequate fetal nourishment.¹⁵

The class Ib nonclassical HLA-E, HLA-F, or HLA-G molecules share a similar overall structure, but differ in their peptide-binding cleft. All have relatively few polymorphisms. HLA-E is specialized to bind the leader peptide of most HLA-A and HLA-B molecules cleaved off during synthesis. The extent of loading of HLA-E molecules becomes a reflection of the rate of class Ia molecule synthesis. Inhibitory CD94/NKG2A expressed on NK cells engages leader peptide-loaded HLA-E molecules and this holds the killing function of these cells at bay. A reduction in the level of class Ia molecule synthesis, *missing self*, as might occur during certain viral infections (Chapter 18), leads to diminished expression of HLA-E-peptide, release of NK cell inhibition, and subsequent destruction of the target cell. A complementary surveillance function monitors for cells under stress, *stressed or damaged self*. Stress induces upregulation of HLA-E, enabling engagement of activating NKR CD94/NKG2A, making the stressed target cell a target for the NK cell. This is paralleled by the MIC-A/B system. This dual regulatory mechanism plays a major role in maintaining the integrity of the intestinal epithelium.

HLA-G is highly expressed by placental trophoblast cells. It is distinguished by a series of alternative splices that result in either a membrane form lacking combinations of α_2 or α_3 domains or a soluble isoform that lacks the transmembrane domain. HLA-F has a small binding cleft that does not contain peptide and its functions are not well understood.

The α -chains of a separate group of class I molecules, CD1A through CD1E, are not encoded in the MHC, but on chromosome 1. These molecules also associate with β_2 -microglobulin, but exhibit limited genetic polymorphism. They present nonpeptide antigens, including microbial lipids and glycolipids, to $\gamma\delta$ or NKT cells.

HFE, the hemochromatosis gene, a member of the class I family, regulates iron absorption by controlling the interaction of the transferrin receptor with transferrin. HFE has a binding cleft that is too small to contain a peptide. HFE defects can lead to hereditary hemochromatosis or porphyria.

■ HLA ALLELE DETECTION, NOMENCLATURE, AND INHERITANCE ■

The initial recognition of HLA molecules involved the use of human allosera that arose from alloimmunization during pregnancy or transplantation. The resulting nomenclature reflects the history of this discovery effort. Allotypes were designated by numbers, such as HLA-A2, HLA-B27, and HLA-Cw6; and the numbers of the HLA-A and HLA-B antigens are nonoverlapping. The letter 'w,' initially used to refer to a tentative workshop category, was retained for the HLA-C allotypes to prevent confusion with the complement components C2 and C4 that also map in the MHC. Some specificities were found not to be shared by numbers of allotypes. These are designated public specificities or epitopes. HLA-Bw4 and HLA-Bw6 are examples that are now known to define motifs recognized by the KIR receptor 3DL1.

Allosera were supplanted in order by gel analysis, DNA-based hybridization, and direct sequencing. Using these techniques, 2899 alleles of expressed class I and II HLA genes could be recognized by the end of 2007. These include 617 HLA-A, 960 HLA-B, 335 HLA-C, 9 HLA-E, 21 HLA-F, and 28 HLA-G named class I alleles, as well as 626 HLA-DRB, 34 HLA-DQA1, 87 HLA-DQB1, 23 HLA-DPA1, and 127 HLA-DPB1 alleles. The current nomenclature is a modification of the serologic classification extended to four-digit allele designations, so that HLA-A2 becomes HLA-A*0201. Currently 115 alleles differing at the nucleotide level have been identified that encode the HLA-A2 serologic specificity and belong to the same allele family. They are designated HLA-A*0202 through HLA-A*0296. The first four digits are used to distinguish alleles encoding different amino acid sequences. Alleles that have distinguishing silent nucleotide changes are assigned additional digits, so there are HLA-A*02010101, etc. Sequencing has also revealed null alleles that contain stop codons, e.g., A*0215N. Since there is no transcribed and expressed product, individuals with this null allele are not tolerized to determinants expressed by HLA-A2 molecules and may make a strong alloimmune response to tissue expressing a nonnull HLA-A2 allotype. Different alleles occur at highly different frequencies among different ethnic and racial groups (Table 5.2). Table 5.2 also illustrates the peptide-binding motifs of these allotypes.¹⁶

Due to the infrequency of cross-overs, combinations of genes forming haplotypes are the unit of MHC inheritance. This is measured by the Δ value of linkage disequilibrium. For example, among the Irish the haplotype frequency of HLA-A*0101 is 20.2%, of HLA-B*0801 is 16.2%, and of DRB1*0301 is 16%. If each allele occurred separately, the expected frequency of finding an HLA-A*0101-B*0801-DRB1*0301 individual would be $20.2 \times 16.2 \times 16 = 0.052\%$, but the observed frequency of the HLA-A*0101-B*0801-DRB1*0301 haplotype is 9.0%, yielding a linkage disequilibrium Δ value of $9.0 - 0.052 = 8.5$. There are two ways of counting the frequency of HLA alleles: gene or haplotype frequency. The gene frequency counts the number of alleles per haploid chromosome, totaling 100% or 1.0. The phenotype frequency, which enumerates the frequency of alleles in a population of diploid individuals, can total up to 200%.

The genetic relationships among members of a family are important for disease inheritance and transplantation. Each parent shares one haplotype with each of their children and always differs by one haplotype. Two siblings may share two, one, or no haplotypes, and thus range from being HLA-identical, through haplo-identical, to HLA-disparate.

■ PEPTIDE-BINDING FUNCTION ■

The peptide is a critical structural component of the classical class Ia and II MHC molecules. If a peptide is not loaded into a molecule or somehow escapes from the binding groove, the molecule becomes unstable and disassociates into its component chains. The purpose of this instability reflects the cell-specific surveillance function of these MHC molecules and prevents the passive acquisition of peptides from the milieu surrounding the cell that would subvert immune recognition.

Allotypes are generally distinguished by different patterns of peptide binding, as illustrated for selected HLA-B molecules in Table 5.2. In class I molecules, one or a few amino acid changes may considerably alter the functional consequences of a pocket and confer different binding properties.

In a healthy nonendocytosing cell, MHC molecules are filled with a variety of peptides from self molecules. Even during viral infection or upon pathogen phagocytosis the number of nonself peptides may not be high. Binding to MHC class I molecules follows several rules. Usually peptides are nine amino acids in length and are always oriented with their NH₂ terminus to the 'left' (Fig. 5.2).

The biological consequences of the different patterns of peptide binding are significant. In the response to human immunodeficiency virus-1 (HIV-1: Chapter 37), the presence of HLA-B27 is associated with long-term nonprogression to acquired immunodeficiency syndrome (AIDS), whereas HLA-B35 denotes rapid progressors.¹⁷ One of the striking correlates with these two HLA alleles is the number of different peptides in the HIV envelope that can bind to either type of HLA molecule. Fifteen different envelope peptides can bind to the HLA-B27 molecule, while no peptide contains motifs that preferentially bind to HLA-B35. The HIV infection is controlled by a CD8 T-cell response for a period of years, and the length of this time is proportional to the number of viral peptides recognized. The virus progressively mutates the anchor residues and the amino acids recognized by T-cell clones to evade presentation and identification.¹⁸

■ CONTRIBUTION OF MHC AND PEPTIDE TO THE MOLECULAR BASIS OF T-CELL RECOGNITION ■

Because the TCR repertoire is selected on self p-MHC, the molecular basis of MHC restriction of peptide recognition is affected by MHC residues that influence the peptide binding as well as by polymorphic MHC residues that contact the TCR. The specificity of recognition depends on particular amino acid differences. The dual dependency on peptide and MHC is well illustrated by a classic experiment that was performed with T-cell clones which recognize hepatitis B virus. The two T-cell clones were derived from an HLA-A*3101/A*6801 patient with hepatitis B virus hepatitis. In examining the HLA-restricted cytotoxic T-cell response to the hepatitis B nucleocapsid core antigen (HBcASg), Missale et al. identified a CTL epitope recognized by both clones that maps to a 10-residue sequence from amino acids 141–151 of HbcAg (Table 5.3).¹⁹ HLA-A31 and HLA-Aw68 each proved to bind the same peptide, even though their amino acid sequence in domains 2 and 3 differs by 13 amino acids. The peptide-binding motif of A*3101 A*6801 and 10 of the amino acid differences influenced only the peptide-binding

pockets. Although both MHC molecules bound the same peptide, the killing of T-cell clone 3D11 was completely restricted to HLA-A*3101 and that of 2D7 was restricted to HLA-A*6801 (Table 5.3). Subsequently it was shown that the same peptide is recognized differently, with the TCR of clone 3D11 recognizing the E at 145 (P5) while 2D7 recognized the two Ts at 146 and 147 (P6, P7). These recognition patterns reflected differences in three TCR contact amino acids on the two α -helical rims of the two HLA-A molecules, which contribute to the separate HLA-A allotype restriction of each clone.

AUTOIMMUNE DISEASE

Autoimmune diseases are generally complex diseases with indeterminate modes of inheritance that are influenced by the number and kind of susceptibility alleles that segregate at several loci throughout the genome. A monozygotic twin concordance rate on the order of 50%

suggests that stochastic events, such as TCR repertoire formation, as well as extrinsic environmental effects likely play a role in onset and progression of the disease. The primary susceptibility to develop most autoimmune diseases is associated with alleles or haplotypes of either class I or class II MHC loci.¹

One of the more extraordinary observations in the MHC field was made in 1973 when the frequency of HLA specificity HLA-B27 was found to be 95% in those with the disease *ankylosing spondylitis* compared to 2–3% in healthy controls. The odds of being HLA-B27-positive if one has ankylosing spondylitis are 0.95/0.05 = 19, and the odds of being HLA-B27-positive if one is a control are 0.02/0.98 = 0.02. Thus, the odds of developing ankylosing spondylitis if one is HLA-B27-positive is 19/0.02 = 950:1, surely an impressive observation that implicates HLA-B27 in the pathogenesis of ankylosing spondylitis. However there are several points about this approach. First, ankylosing spondylitis is a relatively rare disease with a prevalence of ~130 per 100 000, or 0.013%. For every HLA-B27 patient with ankylosing spondylitis there are over 15

KEY CONCEPTS

CLASS II MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) GENES

- >> The class II region contains the genes encoding human leukocyte antigen (HLA)-DR, DQ, and DP, which are principally concerned with CD4 T-cell peptide recognition, and PSMB8, PSMB9, TAP1, and TAP2, which help process peptides for class I molecules
- >> During the synthesis of MHC class II molecules, occupation of the peptide-binding groove by the N-terminus of the invariant chain prevents the binding of self-peptides
- >> MHC class II molecules are constitutively expressed on professional phagocytes, thymic epithelial cells, and activated T cells
- >> Interferon- γ induces the expression of MHC class II molecules on a wide variety of stromal, parenchymal, and vascular cells

healthy HLA-B27-positive persons without the disease ($2.0/(0.013 \times 0.95)$). Second, the impressive odds ratio, although mathematically correct, somewhat numerically overstates the impact of HLA-B27, since it is a ratio of two ratios. Third, it is quite clear that the HLA-B27 allele conferring susceptibility does not differ from the 'wild-type' allele found in the healthy population and is also positively selected in the overall population. Fourth, there are 44 alleles of HLA-B27, of which HLA-B270502 is the most common, and not all alleles are associated with susceptibility to ankylosing spondylitis. The B27 molecules associated with susceptibility are often distinguished by the presence of a cysteine in the P2 pocket that can potentially dimerize to another HLA-B27 molecule. This allele has a tendency to fold slowly and somewhat unstably, as well as a peptide-binding motif that often recognizes a large proportion of peptides. Lastly, although it has been three decades since the initial observation was made, we still do not have a precise and certain understanding of how the presence of the HLA-B27 alleles results in the autoimmune injury underlying ankylosing spondylitis, nor indeed how HLA alleles confer susceptibility for most of the many autoimmune diseases that have a large component of their susceptibility in the MHC. Nevertheless, it appears to be the particular HLA-B27 allele, rather than a gene in linkage disequilibrium with the HLA-B27 allele, because the association of the particular HLA-B27 allotypes with susceptibility appears to map to the sequence of the allele.

THE CLASS II REGION

The genes of the class II region are almost exclusively concerned either with recognition of peptide expressed by CD4 T cells or with processing of peptides for class I molecules. As with MHC class I molecule, self-peptide-MHC class II complexes expressed in the thymus positively and negatively select the CD4 TCR repertoire according to the particular MHC class II allotypes. In the course of an immune response, nonself proteins are endocytosed by 'professional' phagocytes, processed and reduced to nonself peptides, and presented by class II molecules expressed on these cells for recognition by the TCRs of CD4 T cells.

Following endocytosis, extracellular pathogens and protein antigens are digested in lysosomes to form peptides that are loaded on the MHC class II molecules that traffic to the endosome.²⁰ Invariant chain plays a critical role in the class II pathway, because its C-terminus contains a recognition motif that redirects the molecule to the endosome rather than to the cell membrane. The N-terminus of invariant chain occupies the peptide-binding groove during its synthesis in the endoplasmic reticulum so no endogenous peptide can load the class II molecule during its time in the endoplasmic reticulum. The acidic enzymatic environment of the endosome degrades the invariant chain to a CLIP (class II-associated invariant chain peptide) that is subsequently removed to allow peptide binding. The class II molecule is then free to travel to the cell membrane where it presents its newly acquired peptide to CD4 T cells (Chapters 6 and 7).

Of the 18 expressed genes in the class II region (Fig. 5.1), 11 encode either the α -chains, HLA-DPA, HLA-DQA, and HLA-DRA; or the β -chains, HLA-DPB, HLA-DQB, HLA-DRB1, HLA-DRB3 of the classical heterodimeric HLA-DP, HLA-DQ, HLA-DR molecules; or the analogous α - and β -chains of HLA-DM and HLA-DO molecules.⁵ In some haplotypes the HLA-DRB3 gene is replaced by HLA-DRB4, HLA-DRB5, or a pseudogene. With the exception of HLA-DRA, classical class II molecules are highly polymorphic. As with class I molecules, this polymorphism determines the particular peptides they present to CD4 T cells, thus regulating their immune response. The nonpolymorphic nonclassical class II molecules HLA-DM and HLA-DO are exclusively expressed in endosomes. They regulate peptide binding to the classical MHC class II molecules. HLA-DM, a peptide editor, plays a central role in peptide loading of MHC class II molecules by helping to release the CLIP from the peptide-binding site and facilitate entry of peptides that bind with higher affinity.²¹ HLA-DO interacts with HLA-DM but its expression is more restricted. Analogous with the class I region, there are a number of pseudogenes in the class II region, reflecting the number of duplication events that have shaped the number and arrangement of genes in this region.⁵

Four genes in the class II region are involved with processing and loading peptides on to class I molecules (Fig. 5.1). PSMB8 and PSMB9 are proteasome subunits and TAP1 and TAP2 transport the peptides from the cytoplasm to the endoplasmic reticulum. Of the three remaining expressed genes of the class II region, one, butyrophilin-like 2 (BTNL2), has a potential immune function. BTNL2 has been implicated in susceptibility to sarcoidosis.

CLASS II MOLECULES

Although the conformation of the classical class II molecules, HLA-DP, HLA-DQ, and HLA-DR is similar to that of class I molecules, there are several key differences (Fig. 5.3). Unlike class I, which encodes the peptide-binding pocket in a single protein chain, class II molecules are constructed from two structurally homologous α - and β -chains that each contributes half of the peptide-binding groove. Both of these molecules are encoded within the MHC. The α_2 domain of the α -chain contributes the left four strands of the β -pleated sheet floor and the upper α -helix, while the β_2 domain of the β -chain contributes the right four strands of the β -pleated sheet floor and the lower α -helix. The α_3 and β_3 domains, similar to the class I α_3 domain, form a supporting stalk and are each connected to transmembrane and intracytoplasmic domains.

Fig. 5.3 Major histocompatibility complex (MHC) class I and II molecules have a homologous domain organization, but a different chain structure.

The peptide-binding region differs from that of the class I molecule in that the antigen-binding groove is open at both ends. Thus, the MHC class II heterodimer does not interact with either the N- or C-terminus of the peptide. Accordingly, the MHC class II-binding peptides may be of varying lengths, up to about 30 amino acids, and their N- and C-termini extend outwards from the peptide-binding groove. Side chains in the middle of the peptide tether it to pockets within the groove.

The contribution of the α - and β -chains to the polymorphism in the HLA-DR molecule differs from that found in HLA-DP and HLA-DQ molecules. In the latter, both the α - and β -chains are polymorphic and each contributes to overall peptide-binding characteristics of the molecule. The α - and β -chains in HLA-DP and HLA-DQ can come either from genes on the same haplotype, *cis*, or from the α - and β -chain genes on opposite haplotypes, *trans*. This complementation between genes encoded by different parental haplotypes generates novel MHC molecules with peptide-binding characteristics not found in either parent. This is the mechanism involved in the determination of *celiac disease* susceptibility, where the inheritance of the DQA1*0501 allele and the DQB1*0201 allele confers disease risk whether or not the genes are inherited on the same paternal or maternal haplotype.

The α -chain gene of the HLA-DR molecule lacks immunologically significant polymorphisms and all of the considerable diversity in peptide-binding function arises from the more highly polymorphic DRB chain alleles. The structure of the DR region between DRA and DRB1 is a complex polymorphic region that varies across different haplotypes.⁵ While all MHC haplotypes have a single DRB1 locus, additional DRB genes are found in most, but not all, haplotypes. These additional genes vary in number and position, reflecting their origin by duplication and recombination events. The DRB3 locus is present in DRB1*03 and *11, *12, *13, and *14 haplotypes and encodes the HLA-DRw52 specificity. The DRB4 locus is present in evolutionarily more ancient DRB1*04, *07, and *09 haplotypes, and encodes the DRw53 specificity. The DRB5 locus is present in DRB1*15 and 16 haplotypes and encodes the DRw51 specificity. These haplotypes also vary in intron sequences, repeat elements, and the presence of pseudogenes. Differences in genomic structure between the haplotypes prevent homologous meiotic pairing and may

contribute to linkage disequilibrium by suppressing recombination. Similar complex polymorphisms are seen in the class III region.

The expression of MHC class II molecules is much more intricately regulated than that of class I MHC.²² In addition to professional phagocytes, class II molecules are expressed on thymic epithelial cells and activated T cells. Interferon- γ expression occurring during tissue infiltration by activated T cells or NK cells also induces MHC class II molecule expression on a wide variety of stromal, parenchymal, and vascular cells. The MHC class II molecule expression is also regulated within a lineage according to developmental stage. In the myeloid lineage committed neutrophil progenitors express class II molecules through the myeloblast stage. Expression diminishes upon maturation of monocytes to macrophages, unless it is reinduced by interferon- γ . Expression in B cells is lost upon their differentiation into plasma cells.

Expression of class II molecules is regulated by a promoter located within 150 basepairs of the transcription initiation site in exon 1. A variety of cooperative trans-acting factors bind to the promoter. MHC2TA is a critical coactivator for MHC class II expression that binds to these subunits. Genetic defects in the expression of these factors results in the *bare lymphocyte syndrome*. MHC2TA is induced in activated T cells and by interferon- γ , resulting in upregulation of class II MHC expression. This upregulation is opposed by TH2 or antiinflammatory cytokines such as transforming growth factor- β , interleukin (IL)-4, and IL-10.

CLASS II-ASSOCIATED AUTOIMMUNE DISEASES

Susceptibility to a large number of autoimmune diseases, especially those characterized by autoantibodies, is influenced by a number of MHC class II alleles. The inheritance of *rheumatoid arthritis* is an interesting instance where susceptibility maps to a set of HLA-DRB1 alleles, all of which are intriguingly characterized by similar amino acid motif involving positively charged amino acids around position 70 in the β -chain, that has been designated the *shared epitope*.^{23, 24} The presence of two alleles of this group increases susceptibility and favors development of more severe disease.²⁵ The region around position 70 is involved in the formation of a peptide side chain binding pocket. It also interacts directly with the TCR. The apparent functional equivalence or identity by state of the DRB1*0101, *0401, *0404, *0405, *0408, *1001, and *1402 that confer susceptibility to rheumatoid arthritis explains why earlier linkage studies greatly underestimated the contribution of the MHC to disease genetics.²⁶

THE CLASS III REGION

The MHC class III region is the shortest (0.7 Mb), most gene-dense (58 genes; one every ~15 kbp of DNA), and evolutionarily the most ancient and stable within the MHC since it contains highly conserved genes and the fewest pseudogenes.⁵ It is delimited by the telomeric BAT1 and the centromeric NOTCH4.

The MHC class III region contains both nonimmune genes and immune-related genes involved in inflammation. However, none of these genes is involved in the presentation of peptides. Among the immune-related genes are three encoding complement components C2, fB, and C4, three members of the tumor necrosis factor (TNF) family, TNF, LTA, and LTb, members of the Ly6 superfamily, three genes encoding heat shock protein and the gene for the receptor for advanced glycation products, RAGE. Among nonimmune genes is 21-hydroxylase (CYP).

Additionally, Notch 4, PBX, and SK12 are interesting because they are ancient genes that substantially predate the adaptive immune system and form part of the fundamental framework of the MHC in many species. The region is distinguished by remarkably little recombination.

With one major exception, there is little evidence of gene duplication in the class III region. The exception is the polymorphic subregion that contains the C4 and 21-hydroxylase loci. This region is designated RCCX (Fig. 5.1) because it is composed of tandem duplications of RP, C4A/B, CYP21, and TNXB.⁵ Ten different haplotypes of this subregion exist that differ markedly in terms of gene content and arrangement with one, two, or three copies of the genes, analogous to the complex haplotype organization of the DRB region. The C4 gene is duplicated, resulting in two functionally different forms C4A (acidic) and C4B (basic) (Chapter 20). Some individuals may lack either the C4A or C4B gene and the variation in copy number of the C4 gene, mainly between 2 and 6 copies, presumably contributes to the large range of stable normal C4 levels. Similarly, the 21-hydroxylase gene is duplicated, as CYP21A a pseudogene and CYP21B.²⁷

EXTENDED CLASS I AND CLASS II REGIONS

The most telomeric member of the class I family, HFE marks the beginning of the extended class I region that ends with MOG. Its 4 Mb contains large clusters of histone, tRNA, zinc-finger and ribosomal protein genes that are seemingly unrelated to the regulation of the immune response.²⁸ It also contains two clusters of olfactory receptor genes that have been considered to play a part in mating choice. Since these olfactory receptor genes are in linkage disequilibrium with class I and class II HLA alleles, they could thus influence selection of polymorphic HLA genes.²⁹ The presence of linkage disequilibrium also extends centromeric from the MHC to kinesin family member C1, KIFC, that is not structurally related to the class II MHC gene family. This region contains TAPBP, TAP-binding protein (tapasin), a transmembrane glycoprotein that mediates interaction between newly assembled MHC class I molecules by binding to TAP1.

FUTURE LEARNING AND RESOURCES

This chapter provides only a limited sketch of this fascinating but complex topic. The reader is referred to *The HLA Facts Book*⁶ for a more detailed and very accessible presentation of much additional information. There are also a number of websites with extremely useful information. Four stand out in terms of their utility and the curated quality of the information. The IMGT/HLA database (<http://www.ebi.ac.uk/imgt/hla/index.html>) contains all MHC sequences and has a variety of sequence alignments of different alleles as well as specialized sequence searches. The National Center for Biotechnology Information maintains dbMHC that includes several components of the international histocompatibility working group (IHWG) that are of interest. Among these are the anthropology database that contains HLA class I and class II allele and haplotype frequencies in various human populations: <http://www.ncbi.nlm.nih.gov/projects/mhc/>. Information about the genes and the genetic organization of the MHC is contained in several sites, but perhaps the most comprehensive and comprehensible is that using the Entrez search engine: <http://www.ncbi.nlm.nih.gov/gquery/gquery.fcgi?tool=toolbar>.

Antigens and antigen processing

John R. Rodgers, Robert R. Rich

6

A century ago the composite word 'antigen' referred to 'that which generates antibodies'. This tautology developed before the concept of a 'receptor', before the definition of macromolecular proteins, before a kinetic theory of binding specificity, and before it was known that antibodies actually bind to antigens. The antigen-antibody tautology remains central to our concepts of immunity and to the tautology of 'self' and 'non-self'.

At a molecular level, an 'antigen' can be defined today as any molecule recognized by (i.e., binding specifically to) the antigen-binding domain of an 'antigen receptor' (antibody or T-cell receptor – TCR) (Fig. 6.1). The antigen bound by a particular antigen receptor is sometimes called its *cognate antigen*. The concept of a cognate antigen is useful when identifying the molecular rules governing antigen-antigen receptor

interactions, for predicting antigens from sequence and structural information, for designing subunit and genetic vaccines, and for understanding what the immunologist means by such terms as 'self' and 'nonself'.

Because the definition of antigen remains tautological; it requires us to know in advance what antigen receptors are, even though they must ultimately be defined as 'those structures that bind and distinguish among different antigens'. At the biologic level it is sufficient to appreciate that if an organism has already generated antibodies or TCR specific for the antigen, that antigen may be identified by means of an assay appropriate for study of the binding interaction between the two entities.

This definition begs the question of why some molecules, albeit in principle capable of binding one or more antigen receptors, do not *generate* antigens in a given organism. Three factors impinge on this functional definition. The first concerns mechanisms that affect the structure and conformation of the antigen: antigen processing (covered in this chapter) and antigen presentation (Chapter 7). The second category includes mechanisms of tolerance that delete or inactivate antigen receptors – for according to the molecular tautology mentioned above, an antigen that has no 'cognate' antigen receptor in some specific context does not function as an antigen, even if it possesses the requisite structural properties. Finally, we must consider those factors that allow the clonal expansion and functional expression of antigen receptors – that is, those permissive factors that allow an individual to express functionally an acquired immune response to the antigen.

It will require much of the rest of this book to explore these functional categories. Still, special terms make the practical distinctions required by the two kinds of definition. Thus, 'hapten', 'epitope', and 'determinant' are terms that refer to the structural definition of a cognate antigen. When a structure lacks the permissive factors required to stimulate the production of cognate antigen receptors, we call this an 'incomplete antigen'. Antigens that actually *induce* immune responses are called 'immunogens' or 'complete antigens'.

Antigens recognized by antibodies are chiefly recognized directly, in their macromolecular form, whenever the macromolecular conformation allows epitopes to be exposed on the molecular surface. In contrast, antigens recognized by T-cell receptors are acquired by an antigen-presenting cell in a macromolecular form, but are then *processed* into epitopes.

Fig. 6.1 Two definitions of antigen. Epitopes form the complementary molecular surfaces that engage the antigen-binding sites of clonally selected antibodies or T-cell receptors. Complete antigens or immunogens for B cells also carry T-cell epitopes. These must be released by antigen processing for presentation by major histocompatibility complex (MHC) molecules. In this model, the APC is a B cell expressing its own membrane-bound immunoglobulin. A dendritic cell would acquire antigen-antibody immune complexes through the binding of the antibody to an Fc receptor.

In the remainder of this chapter we discuss, first, the biochemical aspects of antigens recognized by antibodies and TCR, and second, the biochemical processing steps that convert large molecules into structures that bind antigen receptors. At a functional level, this chapter will deal with only one key aspect of complete antigens: the need for more than one epitope per antigen. For example, most antigens for antibodies are not *immunogenic* unless they also contain epitopes for helper T cells. Important exceptions to this generalization are the ‘T-independent’ antigens, described below, which either receive a separate signal through a conserved pattern recognition receptor or contain two or more repeating epitopes. Additionally, molecules that bind TCR are not immunogenic unless the T cell is activated. Thus, a B-cell response to a cognate antigen requires accessory or helper T antigens, which themselves are not cognate with the B-cell receptor (antibody). The equivalent cognate antigens for T cells are generated by *antigen processing*. Still, most potential immunogens for T cells will not be immunostimulatory unless accompanied by *adjuvants* that help activate *antigen-presenting cells*, such as dendritic cells.

■ ANTIGENS AS LIGANDS FOR ANTIBODIES ■

Using appropriate carriers and adjuvants, antibodies can be raised *in vivo* against almost any chemical moiety.¹ Ligands include naturally occurring proteins, lipids, steroids, sugars and nucleic acids, as well as synthetic compounds. Here the only limitation appears to be that it is difficult to raise antibodies against molecules to which the immune system has become tolerant – especially ‘self’ molecules expressed extracellularly. Nevertheless, it is often possible to trick the immune system into generating autoreactive antibodies, and many of these arise in autoimmune reactions. Similarly, bacteriophage libraries of recombinant antibodies (*phage display libraries*) can be screened for almost any chemical specificity without regard for self/nonself discrimination.

Haptens (from a Greek word meaning ‘to hold’) are the smallest molecular structures with sufficient molecular complementarity to bind antibodies, and are thus the smallest compound for which enzyme-linked immunosorbent assays (ELISA) or radioimmunoassays (RIA) can be devised. A classic example is the chemical moiety dinitrophenol (DNP), which consists of a hydrophobic aromatic ring with three polar side chains. A modern example of a hapten of great use to basic researchers is phosphotyrosine, a moiety found on many proteins subject to regulation. Haptens are too small to be complete antigens. Therefore, in order to raise hapten-specific antibodies, the moiety is chemically coupled to a

highly immunogenic carrier protein that contains a large number of epitopes for B and T cells. Immunization of animals with haptenated carriers stimulates a polyclonal antibody response that contains mostly antibodies specific for carrier epitopes not related to the hapten, as well as a useful subset with specificity for the hapten itself.

There is no obvious upper limit to the size of an antigen. For example, antibodies are routinely used to tag mammalian cells for flow cytometry in the laboratory, or to opsonize bacteria *in vivo*. Thus we can use ‘antigen’ loosely to refer to complex structures (virus particles, entire cells) or mixtures (tumor or mycobacterial extracts). More typically, we conceive of antigens as specific macromolecules – hence the entire cluster of differentiation (CD) nomenclature for the definition of cell-surface molecules.

Such structures or mixtures actually contain many different cognate molecular structures that bind distinct antigen receptors. Jerne² coined the useful term ‘epitope’ to refer to that part of the antigen that forms direct molecular contacts with the antigen-binding site of the antibody. We also use ‘epitope’ to refer to that part of an antigen peptide that engages the TCR, including those residues that primarily engage the major histocompatibility molecule (Fig. 6.1). Epitopes thus tend to be subsets of the complete antigen. In Jerne’s system, ‘haptens’ are a subset of epitopes and thus can be even smaller than a typical epitope. The antigen-binding site of antipolysaccharide antibodies holds up to six sugar residues; antipeptide antibodies accommodate up to four amino acids; somewhat larger epitopes can be recognized on native protein antigens. The epitopes recognized by TCR are about the same size – typically peptides of a dozen or fewer amino acids.

Antibodies can bind antigens both in solution and independently of any other molecule. This property differentiates antigens for antibodies from those typically recognized by TCR, which instead recognize their epitopes bound to major histocompatibility complex (MHC) molecules (Chapter 5). The majority of protein epitopes, however, do depend on the conformation of a peptide or group of peptides within the three-dimensional structure of a folded protein.³ These are termed *conformational* epitopes. These may vanish if a protein enters a different allosteric state or is denatured, as in most Western blot assays. A major subset of such epitopes are *discontinuous* epitopes. These are composed of noncontiguous amino acids or very short oligopeptides that are brought into close proximity in the native three-dimensional form of the protein. As a result, most epitopes of native proteins are located in exterior loops and can be predicted by a variety of structure-prediction strategies.⁴ In contrast, the epitopes that are detected by Western blotting are typically neither conformational nor discontinuous: they are comprised of haptens or of a continuous or ‘linear’ sequence of amino acids that is not structurally disrupted by the denaturing conditions of the assay. Similarly, epitopes bound by TCR are short linear peptides within the antigen-binding cleft of an MHC molecule.

Neutralizing antibodies inactivate the activity of toxins, pathogens, enzymes or other proteins. The ‘inhibitory’ antibodies produced by many hemophilia patients receiving clotting factor replacement therapy are of this type. Neutralizing epitopes on virus particles may represent a transition state or otherwise altered conformation stabilized by the antibody that results in noninfectious viral particles. ‘Neutralizing’ antibodies in other cases refer to those that fix complement and destroy virus infectivity by physical destruction of membrane-enclosed viruses.

Not all antibodies that bind to a pathogen are strictly neutralizing. For example, most antibodies specific for the HIV gp120 envelope protein are not neutralizing, and some even facilitate the uptake of virus

■ KEY CONCEPTS

ANTIGENS FOR B CELLS

- >> Immunogens contain
Epitopes that bind to the antigen-binding sites of antibodies
Class II epitopes for T helper cells.
- >> Haptens can have almost any chemical nature.
- >> Epitopes on native proteins can be discontinuous segments of amino acids at the cell surface.

into vulnerable cells such as monocytes. Nonetheless, nonneutralizing antibodies can still block function. For example, anti-insulin receptor antibodies can prevent insulin from gaining access to its receptors. Other antibodies probably block function by clearing ligands. For example, many hepatitis C patients receiving interferon therapy develop anti-interferon antibodies that clear therapeutic interferon from the bloodstream. Immunization with partially denatured proteins or with synthetic proteins may elicit antibodies recognizing epitopes that are independent of a rigid conformation. Such *nonconformation-dependent* antibodies are useful, especially in Western blot assays. This is the basis of the widely used assay for HIV infection.

ANTICARBOHYDRATE ANTIBODIES

T-independent (TI) antigens are typically polysaccharides with the ability to induce B-cell proliferation and antibody secretion *in the absence of T cells*. At relatively high doses, TI-1 antigens, typified by lipopolysaccharide (LPS or endotoxin), stimulate polyclonal proliferation of B cells, in part by activating toll-like receptor TLR-4 and its MyD88-dependent signaling pathway (Chapter 3). At lower doses TI-1 antigens stimulate the division of B cells that secrete antigen-specific antibodies. This probably reflects cross-linking surface antibodies by such polyvalent antigens.

TI-2 antigens behave much as do TI-1 antigens at low doses. They include pneumococcal capsular polysaccharides and are probably effective by virtue of their repeating structure: polyvalent antigens can more easily cross-link the B-cell receptor to induce proliferative signals. Consistent with this interpretation, TI-2 antigens stimulate antigen-specific responses in athymic mice but, unlike TI-1 antigens, do not stimulate polyclonal proliferation at high doses.

A classic example of anticarbohydrate immune responses is provided by the human ABO 'blood group' system of antigens, which are expressed in many tissues of the body and by many kinds of bacteria.⁵ The polymorphic ABO locus encodes a glycosyltransferase that functions as a haptanating enzyme in this system. The common O allele is functionally silent. Both active enzymes (alleles A and B) transfer a uridylylated diphosphate (UDP)-charged sugar to glycoproteins and glycolipids. The A and B enzymes use UDP-N-acetyl-galactosamine and UDP-galactose, respectively, as sugar donors.

Individuals expressing the A and/or B alloenzymes express A and/or B-type carbohydrates as self-antigens, and are thus tolerant to them. In contrast, O-type individuals cannot make A or B antigens. As a result, O individuals are *intolerant to these antigens*. Thus exposure to common bacteria induces both anti-A and anti-B antibodies in O-type individuals. Their own blood does not contain either antigen, however, and so they are universal donors. A and B individuals may not donate blood to an O individual, because their donated erythrocytes are rapidly lysed by the recipient's anti-A or -B antibodies through a complement-mediated mechanism. The anti-A and anti-B antibodies of a type O donor could react with recipient erythrocytes but are rapidly cleared by absorption by the other antigen-expressing cell types in the recipient.

Interestingly, the nature of antibody responses to T-independent antigens can provide an insight into important roles of T cells in conventional (T-dependent) antibody responses. For example, T-independent responses generally do not exhibit immunological memory and do not undergo isotype switching with maturation of the response (i.e., antibody responses are of the IgM class), consistent with the known requirement for T-cell help in these features of a typical T-dependent response.

With the exception of the 'T-independent antigens', antigens for antibodies are limited to those that can be coexpressed with antigens for T cells. Without T-cell help, B cells will not respond to antigen stimulation and might be tolerized. As suggested by the absence of classic immunologic memory in T-independent antibody responses, strong secondary T-dependent antibody responses also require that B cells present antigen to T cells, leading to the requirement for T-B interactions. B cells capture *carrier* antigens attached by their hapten-specific antibodies, and then endocytose, process and present them to T cells. The B and T epitopes present in a vaccine do not need to derive from same targeted pathogen. For example, a 'multiantigenic peptide' vaccine might include a strong T-cell epitope for tetanus and an antibody epitope for HIV. Such a vaccine couples a primary response to the HIV epitope with a secondary response to tetanus.

■ ANTIGENS AS LIGANDS FOR T-CELL RECEPTORS⁶ ■

The biochemical definition of antigen indicates that epitopes recognized by TCR should bind directly to them. This is true in some cases, but the affinity of these interactions is usually too weak. Instead, epitopes recognized by T cells are recognized in the molecular context of major histocompatibility complex (MHC) molecules (Chapter 5). This means that such epitopes have two receptors: the MHC molecule, which binds with high affinity, and the TCR, which recognizes the molecular complex of MHC and epitope. Historically, MHC class I and class II molecules were themselves viewed as antigens. 'Major histocompatibility' or 'transplantation' antigens elicit robust antibody responses as well as strong T cell-mediated alloreaactions in mixed leukocyte cultures and tissue transplants. As antigens for antibodies, they behave as conventional protein antigens; it is their ability to stimulate T cells that makes them potent in transplant situations.

MHC molecules typically bind short peptides. The short length of epitopes for MHC class I molecules is enforced by a closed-ended binding cleft that binds both amino and carboxyl termini (Fig. 6.2). In contrast, both ends of the binding cleft of class II MHC molecules are open, allowing longer peptides to bind. Because the ends of these peptides are usually degraded before presentation to T cells, most epitopes for class II molecules are still short – of the order of 15–20 amino acids.

The binding cleft of both class I and class II molecules also interacts with the peptide backbone and two or three of the side chains. The latter are considered *anchor* residues of the epitope and define the *binding motif* of the MHC molecule. Amino acid side chains not used as anchors are potentially available for binding the TCR.

The need for terminal anchoring severely limits the length of epitopes for class I MHC molecules to seven to ten amino acids, though longer peptides can sometimes bind by looping out central residues. In general, the efficacy of a peptide as an epitope correlates with its binding strength. Adding or removing a single amino acid to either end of an 'optimal' peptide often effectively destroys the epitope. As a result, the proteolytic processing pathway (see below) can be very important in generating optimal epitopes from proteins. It is possible for proteins to contain peptide sequences that in their free state bind optimally to MHC molecules, but which are not converted into epitopes *in vivo*.

Antigen recognition by T cells is *MHC restricted* (Chapters 5 and 7). MHC restriction reflects molecular and genetic mechanisms and is explained by the requirement that epitopes for T cells are presented by

MHC molecules. The fact that MHC molecules are highly polymorphic, especially in the sequence positions involved in epitope and TCR contacts, means that antigen recognition by T cells is genetically restricted to only those MHC genotypes expressing the same (*syngeneic*) MHC molecules as the responder. For example, the human class I MHC molecules HLA-A31 and HLA-Aw68 are allelic forms of the same molecule. Both present the same peptide (amino acids 141–151) derived from the core antigen of hepatitis B virus. T-cell clones from an HLA-A31/Aw68 heterozygous patient that recognize this epitope bound to HLA-A31 cannot recognize the same peptide when it is presented by HLA-Aw68 (and vice versa). Such clones are described as HLA-A31 restricted and HLA-Aw68 restricted, respectively.

A given allelic form of MHC molecules recognizes two or three anchor residues with high specificity, severely limiting the ‘universe’ of peptides that it can present to T cells. Two different MHC alleles thus may see radically distinct antigenic universes. The high polymorphism of MHC molecules has three implications for responses to pathogens and vaccines. First, most individuals are heterozygous for each MHC locus, effectively doubling the size of their antigenic universe. Second, although some individuals may be unable to respond to certain pathogens, some are likely to be protected. This may account for the prevalence of certain MHC haplotypes in populations exposed to malaria, and for genetic vulnerabilities or resistance to HIV/AIDS. Finally, epitopes detected by one individual may be invisible to the T cells of another; subunit vaccines effective for some MHC haplotypes may be ineffective for others. For example, the hepatitis B surface antigen subunit vaccine is often ineffective in individuals homozygous for certain *HLA* haplotypes.

How can we rationalize the operation of MHC restriction? Why do T cells not recognize their antigens as do B cells, with no need for antigen presentation? Because alloreactive T cells distinguish between self and nonself MHC molecules, it is tempting to think that MHC restriction mediates self/nonself discrimination. However, it is clear that allospecific antibodies also distinguish self from nonself MHC molecules. MHC

restriction may function in two opposing ways (Fig. 6.3). First, antigen-processing increases the complexity of pathogen antigens by exposing epitopes not available on the surface of pathogens. MHC molecules are ‘merely’ the mechanism for presenting processed epitopes to T cells. MHC polymorphism further increases the size of the species’ antigenic universe. Second, the requirement that T cells do not respond unless activated by co-stimulation from the APC is enforced by anchoring MHC molecules on the APC. This second mechanism thus minimizes autoimmunity. In this view, the experimental observations of genetic MHC restriction and alloreactivity are by-products of the polymorphism of MHC molecules.

Ligands for MHC molecules are usually oligopeptides, but there are notable exceptions. In particular, the class I-like molecule CD1 presents certain lipids, such as are found in mycobacteria. Even conventional oligopeptide epitopes may include modified amino acids such as phosphoserine or sugar residues. Chemically modified self-peptides are major determinants of allergic responses to nonprotein environmental agents, such as metals, cosmetics and antibiotics. Mediators of these responses

Fig. 6.2 Peptide binding by MHC class I and II molecules. Class I molecules are usually closed at both ends. The peptide termini must interact with terminal sockets. Peptides that are too long must be cleaved (arrows) prior to entry into the binding site. The clefts of class II molecules are open at the ends, permitting the binding of long peptides.

Fig. 6.3 MHC restriction carries out two critical functions. First, by presenting processed peptides derived from within proteins and pathogens, MHC molecules sample a broader antigenic landscape than antibodies, whose epitopes are surface oriented. Second, naive T cells respond to cognate epitopes only when presented by an activated APC (B) but not when the APC is resting (A). Experimentally observed MHC restriction results when an activated APC cannot present the proper MHC/peptide pair (C).

may be effector T cells, as in cell-mediated contact sensitization, or helper-T cells, as in induction of allergic antibodies.

An important clinical example is the allergic response to penicillin and other β -lactam-based antibiotics (Fig. 6.4). The β -lactam ring can cross-link itself to a patient's own proteins, thereby creating a novel set of potential epitopes. For example, human serum albumin forms adducts with β -lactams at several different lysine residues and at least one serine residue. Penicillin adducts become haptens for antibody responses, but modified peptide epitopes can be presented by MHC class I molecules to CD8 T cells and by MHC class II molecules to CD4 T cells.

SUPERANTIGENS^{7,8}

'Superantigens' are protein antigen-like molecules produced by a diverse array of microbes that interact with MHC class II molecules and TCR in a manner that dramatically increases the frequency of T-cell responses compared to conventional peptide antigens. They include certain bacterial toxins (e.g., staphylococcal enterotoxin A (SEA) and toxic shock syndrome toxin (TSST)) and viral proteins (e.g., mouse mammary tumor virus superantigen). Superantigens are not processed intracellularly. Instead, they bind class II MHC molecules as intact macromolecules and bind outside the peptide-antigen-binding groove. Class II binding is independent of the specific MHC allele (albeit often with a preference for one or more of the major isotypes:

Fig. 6.4 Sensitizing agents create neoantigens by forming covalent adducts with self-proteins. Penicillin allergies involve both antibodies against penicillin and with T-cell responses to penicillin-modified self-proteins. The same chemical reaction that allows penicillin to inhibit peptidoglycan formation in bacteria leads to adduct formation of cellular proteins. Nucleophilic attack by penicillin G (upper left) on the β -lactam ring (shaded) opens the ring and creates an adduct (lower left) with a protein serines (shown) and lysines. The lactam adducts can be presented to B cells as modified self-proteins or processed for presentation by MHC molecules to T cells as lactam-conjugated self-peptides.

DR, DQ or DP). Each superantigen/class II complex binds TCR bearing a characteristic subset of V β families, thereby selectively activating T-cell clones with those TCR. By stimulating large numbers of clones of a specific V β family, superantigens can induce an overwhelming T-cell response with a massive release of cytokines. This can lead to such clinical conditions as staphylococcal food poisoning and toxic shock syndrome (Fig. 6.5).

ANTIGEN PROCESSING FOR CLASS I-RESTRICTED T CELLS⁹⁻¹¹

T cells recognize their cognate antigens in the form of short peptides embedded in MHC molecules. X-ray crystallography shows that roughly 90% of the molecular surface recognized by the TCR is the MHC

CLINICAL RELEVANCE

SUPERANTIGENS AS ETIOLOGIC AND/OR PATHOGENIC AGENTS IN DISEASES

Definite

- >> Staphylococcal food poisoning
- >> Staphylococcal toxic shock
- >> Staphylococcal scalded skin syndrome
- >> Scarlet fever rash

Probable

- >> Guttate psoriasis
- >> Kawasaki disease
- >> Staphylococcal SAg-related glomerulonephritis

Possible

- >> Atopic dermatitis
- >> Chronic plaque psoriasis
- >> Chronic sinusitis and nasal polyposis

KEY CONCEPTS

PROPERTIES OF SUPERANTIGENS

Defining properties

- >> Presented and recognized as an unprocessed, native protein.
- >> Contact TCR and MHC molecules outside the traditional antigen-binding groove.

Specific properties

- >> Selectively stimulate T cells expressing certain TCR V β chains
- >> TCR recognition is not MHC allele restricted.
- >> Stimulate both CD4 and CD8 T cells in an MHC class II-dependent manner.

Fig. 6.5 Antigen processing for MHC class I. Two chief pathways for antigen process intersect within the cytosol. Most endogenous antigens are synthesized on cytosolic ribosomes, processed by proteasomes, and enter the ER through the TAP transporter. A minor set of antigens are processed within the ER from proteins secreted into the ER. Professional antigen-presenting cells transfer endocytosed antigens into the cytosol for processing.

molecule. *Antigen processing* excises these peptides from their parent protein antigens and loads them onto MHC molecules. It is often said that antigens presented by class I MHC molecules are necessarily endogenous, that is, synthesized by the cells that presented them, whereas class II molecules uniquely present exogenous antigens. This makes sense functionally, because CD8 cytotoxic T lymphocytes (CTL) are class I restricted and need to distinguish virus-infected cells (expressing endogenously synthesized viral antigens) from protective phagocytes such as macrophages. In contrast, CD4 T-helper cells are not usually cytolytic, but need to recognize antigens from bacteria phagocytosed by macrophages.

Although this scenario is useful in a conceptual sense, in practice it is too simplistic. For example, virus-specific CTL are primarily activated by cells – chiefly dendritic cells – that are not themselves infected. A variety of mechanisms known as cross-presentation can be used to process endocytosed antigens, including bacteria and apoptotic infected cells, for presentation on class I molecules.¹²

Endogenous peptides presented by class I molecules derive from proteins made on the cell's own ribosomes.¹³ The chief mechanism for degrading large proteins into small peptides is the *proteasome*, a macromolecular tubular structure containing multiple protease activities that cleaves proteins into small fragments of eight to 14 residues.^{14,15} There are at least four mechanisms that feed proteins into proteasomes. First, nascent cytoplasmic polypeptides that fail to fold properly – and most do not – are attacked by enzymes that attach chains of the protein ubiquitin to the protein targeted for destruction. Second, nascent proteins that are translocated into the endoplasmic reticulum endosome but fail to fold properly can be exported back to the cytosol by a protein transporter called Sec61.¹⁶ Third, properly folded mature proteins are ubiquitinated in the course of normal activity – part of

KEY CONCEPTS

ANTIGEN PROCESSING AND PRESENTATION FOR CLASS I MHC

- >> Peptides presented on most cell types are synthesized endogenously.
- >> Peptides acquired through endocytosis by professional APC can be cross-presented.
- >> Most epitopes are processed by proteasomes and enter the ER through the TAP transporter.
- >> Peptides of 8–10 amino acids are bound at both termini within the binding cleft.

the normal course of protein turnover. Finally, in cross-presentation, proteins engulfed by phagocytes are partially degraded in lysosomes before transfer – through poorly understood mechanisms – into the cytosol.

Proteasomes preferentially cleave proteins after amino acids with acidic side chains (glutamine; aspartamine). However, interferon- γ (IFN- γ) induces the expression of two additional proteasome subunits, the MHC-encoded low molecular weight proteins (LMP). Exchange of the LMP subunits into proteasomes shifts the cleavage pattern towards peptides terminating in basic or hydrophobic residues, which are favored by many class I MHC molecules.^{14,15} This may be one subtle mechanism by which the immune system can distinguish between self-peptides, which are generated constitutively by proteasomes, and peptides

associated with inflammation, which are generated by LMP-containing proteasomes.

Proteasomal digestion products are in turn recognized by the transporter associated with antigen processing (TAP), a member of the ATP-binding cassette (ABC) transporter family of proteins that includes the multidrug resistance protein and CFTR – the cystic fibrosis transmembrane regulator.

Heterodimers of TAP1 and TAP2 subunits form peptide pumps that burn ATP to drive peptides from the cytosol into the lumen of the endoplasmic reticulum (ER). Patients lacking either subunit of TAP cannot process most MHC class I-binding peptides. Without a ready source of peptides in the ER, class I MHC molecules are themselves unstable and are extruded into the cytosol by Sec61 for proteasomal degradation. TAP mutations are involved in many cases of type I bare lymphocyte syndrome (BLS) (Chapter 35) and many tumor cells lack class I expression owing to mutations in their TAP genes (Chapter 81).

TAP transports peptides ranging in size between six and 20 residues. Several allelic forms exist in humans. The TAP1A and 1C alleles prefer peptides with a basic residue at the carboxyl terminus (a form that is *not* preferentially generated by proteasomes), whereas the TAP1B allele shows no such preference.¹⁷ Few of dozens of studies have found any significant associations between human diseases and TAP alleles, leaving the physiological significance of these allelic forms unresolved.¹⁸

A minor subset of peptides enter the ER independently of TAP through the protein secretory pathway. Nascent polypeptides bearing a signal peptide are recognized and transported into the lumen by the signal recognition particle (SRP). The signal peptide itself is cleaved by a signal peptidase. By inserting the sequence of a CTL epitope behind a signal peptide, this pathway can be used to deliver the epitope directly into the MHC class I loading compartment. Peptides that are too long to bind MHC class I molecules may be retained temporarily in the ER by additional peptide-binding proteins such as BiP, pumped back into the cytosol by an undefined non-TAP mechanism, or trimmed by aminopeptidases (also present in the cytosol) to a size that can bind MHC molecules.¹⁹ One of these, leucine aminopeptidase (LAP), is also induced by IFN- γ .²⁰

The luminal proteases appear quite efficient, apparently reducing the steady-state concentration of free antigenic peptides in the ER to very low levels. As a result of differences in protease specificities and/or kinetic effects, different epitopes may be carved out of the same protein, depending on whether it follows the proteasome/TAP or the secretory pathway into the ER. Finally, different peptides within a single protein may be degraded or protected at different rates, leading to immunodominance of a subset of potential epitopes for a given MHC molecule.

The production of an immunodominant epitope from influenza A nucleoprotein (NP) illustrates how extra-epitope residues might affect nonproteasome, nonubiquitin processing.²¹ The optimal NP peptide in one mouse strain is the nonamer TYQRTRALV. The three C-terminal residues are efficiently removed from a related 12-mer peptide TYQRTRALVRTG. However, an 11-mer, TYQRTRALVTG, is impotent at producing the epitope. The terminal TG sequence represents a 'block' to epitope production. All of these complexities in antigen processing make it difficult at present to predict which potential epitopes, identified on the basis of their ability to bind to class I molecules, will be immunodominant *in vivo*.

CLASS I MHC TRAFFICKING

Nascent class I MHC molecules are inserted into the ER membrane via the protein secretory pathway. Nascent chains bind first to the membrane-bound chaperone calnexin until they begin to fold into association with β_2 -microglobulin light chains (β_2m). Heterodimers of β_2m and heavy chain are released by calnexin and bind the soluble chaperone calreticulin. This assembly engages a *class I loading complex*, which includes a 60 kDa thiol reductase, the TAP heterodimer and another MHC-encoded protein, tapasin.²² Tapasin retains class I molecules in the complex until they bind peptide. MHC molecules failing to attract peptides misfold and are exported by Sec61 to the cytosol. Only those that bind peptide are released by tapasin from the loading complex. They migrate to the Golgi, where they undergo glycan maturation, and then traffic to the cell surface for recognition by CD8 T cells.

The noncanonical antigen processing pathway for MHC class I molecules

Noncanonical pathways for acquiring and processing exogenous antigens are very important for initiating MHC class I-restricted responses, a process mediated by 'professional' antigen-presenting cells (APC) that might not themselves synthesize viral or tumor antigens. The acquisition of such exogenous antigens leads to cross-presentation by APC and cross-priming of T cells.

Cross-presentation of class I-restricted peptides can also inhibit immune responses. For example, antigen-specific B cells endocytose their specific antigens, which they then process for presentation by their own MHC class I molecules. When this happens, antigen-specific B cells may be attacked by CTL. In this way, CTL can suppress B-cell responses to some antigens.

B cells can be extremely efficient as APC in stimulating both CD4 and CD8 T-cell responses to their cognate antigens, while ignoring other antigens. However, in the general case they are vastly surpassed by dendritic cells and, to a lesser extent, by macrophages. A critical difference between these cell types is that whereas B cells internalize their own surface immunoglobulins and the antigens attached to them, they endocytose their own Fc receptors inefficiently, and B cells are nonphagocytic. In contrast, DC and macrophages are phagocytic and efficiently endocytose through Fc and other surface receptors.

Receptor-mediated endocytosis probably accounts for the ability of oligopeptide-binding chaperone proteins (chaperonins) to prime class I-restricted antigen responses to antigens. Heat shock proteins gp60, hsp70, hsp90 and gp96 derived from tumors or virus-infected cells elicit peptide-specific CTL responses. These proteins have been proposed as the basis of experimental vaccines.²³ Whether this pathway for transferring peptides from dying cells is important physiologically is controversial. An alternative mechanism focuses on the release of whole proteins from dying cells. These released proteins can be endocytosed by APC. Other mechanisms of cross-presentation include the engulfment of apoptotic and/or 'necrotic' cells, or the endocytosis of apoptotic bodies and 'exosomes.'

All of these mechanisms lead to the uptake of antigens into the endosomes of APC. Although endosomal uptake is sufficient for MHC class II molecules, which are loaded in endosomal subcompartments themselves, antigens cross-presented by class I molecules must still enter the ER through TAP after transfer from the endosomes into the cytosol.

ANTIGEN PROCESSING FOR CLASS II-RESTRICTED T CELLS (FIG. 6.6)^{24–26}

Antigens presented by MHC class II molecules come from two main sources, autophagy²⁷ of endogenous antigens, and endocytosis of both exogenous and cell surface (endogenous) antigens. Autophagocytosis is the engulfment by lysosomes of internal organelles, including mitochondria and endoplasmic reticulum. It is an active process in all cell types.

MHC class II molecules assemble in the ER, where they associate with *invariant* chain, a 31 Da chaperonin specific for MHC molecules. Invariant chain chaperones nascent $\alpha\beta$ dimers of class II molecules into endosomes. A segment of this chain, called CLIP, blocks class II molecules from binding peptides in the ER. Once in the endosomes, CLIP may be removed along with the rest of invariant chain. Alternatively, a CLIP fragment may be left occupying the binding cleft. Many class II MHC molecules traffic to the cell surface with CLIP embedded.

In the absence of infection, MHC class II molecules are loaded with peptides derived from cellular self-proteins. Macrophages and dendritic cells acquire exogenous antigens through endocytosis (Fig. 6.6). Many surface molecules, such as HIV gp120 protein, are endocytosed through clathrin-coated pits. In *receptor-mediated endocytosis*, surface receptors (such as Fc receptors) drag their ligands (antigen–antibody complexes) into the cell. Very large particles, such as bacteria and opsonized viruses and apoptotic bodies, are phagocytosed. The large phagosome fuses with lysosomes, in which bacteria are killed and fragmented before antigen processing can take place.

Regardless of how they reach the endosomes, protein antigens are unfolded and partially degraded in endosomal and acidic lysosomal sub-compartments by disulfide isomerase (which unlinks disulfide loops) and a variety of proteases. Most peptides presented by class II molecules are processed from parent proteins and loaded on to class II molecules within a specialized loading compartment of the endosome. Within this general scheme there at least two pathways for epitope production. These are distinguishable, in part, by their dependence on the function of DM molecules, which are heterodimers composed of DMA and DMB subunits each of which is phylogenetically related to MHC class II proteins.²⁸ DM catalyze the exchange of CLIP for processed epitopes. Alternatively, in the

KEY CONCEPTS

ANTIGEN PROCESSING FOR CLASS II MHC

- >> Class II MHC expressed constitutively only by professional APC (dendritic cells, macrophages and B cells).
- >> Epitopes presented by professional APC are acquired mostly through endocytosis and autophagocytosis.
- >> Peptides (10–15 amino acids) often have terminal extensions, extending outside the antigen-binding groove.

Fig. 6.6 Two pathways for loading antigens onto class II MHC molecules. Autophagy and endocytosis transfer cytosolic and external antigens, respectively, into the endosomes. Nascent class II molecules are chaperoned to the endosomes from the Golgi by the invariant chain. The DM molecules catalyze the exchange of antigenic peptides for invariant chain. Mature class II molecules recycling from the cell surface can acquire peptides in a DM-independent manner. Antigens binding initially as polypeptides are trimmed into oligopeptides in the endosomes and at the surface.

DM-independent pathway peptides are loaded on to class II molecules recycling from the cell surface in the absence of CLIP.

The initial ligand for binding class II molecules is a large unfolded protein or protein fragment, rather than the oligopeptide ultimately displayed at the cell surface. This MHC–polypeptide complex is the substrate for trimming exopeptidases. Prolines are found near the N terminus of many mature epitopes, and the endosomal aminopeptidases cannot cleave at these proline residues. Trimming of the extra-cleft residues can continue even after the MHC–peptide complex has reached the surface through the activity of the membrane-bound surface enzyme aminopeptidase N (CD13).

As in the case of epitope formation for class I molecules, the initial conformation of the antigen can affect the production of specific linear epitopes. For example, vaccinating mice with synthetic peptides elicits class II-restricted T cells specific for at least two HIV gp160 epitopes. However, only one is detected on infected cells. Similarly, prior denaturation or mutational destabilization of viral influenza hemagglutinin abolishes its ability to be processed for presentation to some T-helper cell clones.

PREDICTING EPITOPES FOR TCR

The critical role of T cell antigens in driving both T- and B-cell responses has fueled attempts to use antigen sequence information to predict T-cell epitopes.

The characterization of *binding motifs* for a large number of class I and a smaller number of class II molecules has facilitated computer-based algorithms for predicting potential epitopes from linear protein sequences. These motifs reflect the chemical affinity of the binding cleft for various amino acid side chains. In many cases it is possible to show that several alleles of class I or class II molecules recognize the same or very closely related epitopes. These groups of MHC alleles are called ‘supertypes’ and can permit the prediction of epitopes for a large number of alleles.^{29,30} However, because of the complexity of endoprotease and exoprotease cleavage during processing of epitopes for both class I and class II MHC molecules, it is difficult to predict whether a given epitope will actually be used *in vivo*.

Because MHC-binding peptides are linear fragments, one might not expect them to coincide with discontinuous and/or surface epitopes detected by antibodies. This is often true, but one notable exception to this statement is the V3 loop of HIV gp120, which exhibits immunodominant

epitopes for neutralizing antibodies overlapping with immunodominant Th epitopes. Such observations are consistent with the idea that antibodies can focus the degradative machinery on selected peptides. Following receptor-mediated endocytosis of antigen–antibody complexes on specific B cells, peptide fragments bound to the antibody might be protected from degradation or diverted into a particular degradation path that would favor the likelihood of their binding a class II molecule.

Structural features of immunodominant T-cell epitopes may reflect the probability of coinciding with a facilitating B-cell epitope and/or other factors controlling degradation rates. One such correlative feature is the aforementioned presence of proline near the N terminus of a number of class II-binding peptides and the propensity of proline to induce turns in protein structures. In this case the unique chemical structure of proline contributes independently to its propensity to induce turns, and to its resistance to proteolysis. Proximity to the protein surface may allow an epitope to unfold more readily, enabling it to bind class II molecules prior to lysosomal degradation. Earlier observations that many T-cell epitopes contained sequences prone to form helices or that were amphipathic had been interpreted as suggesting that such peptides bound as helices within the MHC cleft. X-ray crystallography showed that peptides actually bind in extended conformations, but helicity and/or amphipathicity may well affect the kinetic pathways of intracellular degradation. Such observations help establish criteria to identify likely T-cell antigens. A major criterion is that epitopes should bear sequence motifs that favor binding to self-MHC molecules. A second criterion points to the need for a kinetically favorable proteolytic pathway allowing the cell to produce the epitope in quantities sufficient to promote a T-cell response. Accurate prediction of epitope processing remains beyond current science.

TISSUE SPECIALIZATION AND REGULATION OF ANTIGEN PROCESSING

Not all cell types are equally proficient at processing antigens (Table 6.1). As should be obvious from the preceding discussions, limiting factors in different cells can include differences in endocytosis and phagocytosis rates; the presence of internalizable surface receptors; the relative efficiency of different pathways of proteolysis in different subcellular compartments; the level of expression of specialized antigen-processing molecules such as TAP, LMP, DM and invariant chain; and the level of expression of different MHC molecules.

Table 6.1 Antigen processing in representative cell types

	Feature	Endothelial cells	B cells	Dendritic cells
MHC class I	Expression Antigen acquisition	Constitutive Endogenous	Constitutive Endogenous exogenous (surface Ig-mediated)	Constitutive, Endogenous Exogenous
MHC Class II	Expression Antigen entry	Inducible Surface recycling autophagy	Constitutive, inducible Surface recycling autophagy Ig-mediated	Immature low Mature high Surface recycling autophagy Ig-mediated endocytosis phagocytosis
FcγRII	Expression/function	None	Not internalized	Internalized

Class I heavy chains, β_2 -microglobulin, LMP, and TAP proteins are coordinately expressed in most cell types. Activated lymphocytes express high levels constitutively, whereas fibroblasts and liver cells express intermediate levels. Neurons are almost completely negative for expression of all four. $\alpha\beta$ and γ interferons can increase gene expression of these gene sets in most cell types.

Control of MHC class II expression and its attendant antigen-processing machinery is much more complex. Most cell types do not express MHC class II, DM or invariant chains under any circumstances. Macrophages, immature dendritic cells and B cells express these molecules constitutively at low levels. Upregulation is induced by inflammatory cytokines, especially IFN- γ , in most cells. Inflammatory cytokines, notably tumor necrosis factor- α (TNF- α), can also induce class II molecules and antigen processing in certain otherwise class II-negative cell types, including endothelial cells, dermal fibroblasts, neuronal glial cells and astrocytes. Class II molecules are induced on activated T cells in most species, including the laboratory rat, but notably not in laboratory mice. The ectopic expression of class II molecules and associated self-antigens may play a role in the induction of autoimmunity.

MICROBIAL INTERFERENCE WITH ANTIGEN PROCESSING AND PRESENTATION³¹

Considering the importance of class I-mediated immune responses in antiviral immunity, it is not surprising to find a variety of viral mechanisms for subverting antigen processing. Proteins from several serotypes of human adenovirus, as well as HIV-1 tat protein, inhibit class I MHC transcription. Other viral factors inhibit class I MHC maturation in the ER. Two proteins from human cytomegalovirus (CMV), US2 and US11, destabilize nascent class I molecules in the ER by shunting them into the Sec61 pathway for export into the cytosol before they have a chance to bind peptides.

The CMV US6 and herpes simplex virus ICP47 proteins inhibit TAP function, indirectly starving MHC molecules of peptide. In contrast, the CMV US3 proteins binds class I molecules that have already engaged peptides, but retains them in the ER. To round out these examples, the HIV-1 protein nef binds the intracellular tails of mature class I MHC molecules, targeting them for increased endocytosis and degradation.

A CLINICAL CODA

If microbes can manipulate specific mechanisms of antigen processing and presentation, it should be obvious that human genetic variation in these pathways should be able to contribute to immune competency or, through deficiency, to immune dysfunction. These may result in specific or global defects in antigen processing and recognition, such as the bare lymphocyte syndrome (BLS) (Chapter 35). Type I BLS involves general loss of class I surface expression, typically the result of mutations in the TAP peptide transporter. Type II BLS reflects loss of class II MHC expression. Defects in any of at least four different transcription factors can cause this disease. In type III BLS, defects in the RFX transcription factor depress expression of both class II MHC molecules and the β_2 -microglobulin light chain shared by all class I MHC proteins.

A considerable literature indicates that allergens are unremarkable antigens. Their recognition by B- and T-cell receptors follows all the normal rules of antigen acquisition, processing and presentation. One distinguishing feature of some allergens is the formation of adducts by drugs and environmental compounds, resulting in the formation of neoantigens. Intriguing data suggest that some allergens have intrinsic protease activity that may elicit IgE-dependent allergy.³²

As with allergens, and as expected from our chemical understanding of antigenicity, autoantigens are chemically unremarkable. The principles that govern pathological self-recognition appear to be the same as for healthy self-tolerance or recognition of foreign antigens: the availability of particular processed peptides at appropriate times for tolerance induction of T-cell activation.

Two nonexclusive models have emerged that may begin to account for why certain individuals are predisposed to autoimmunity and why certain self-antigens are likely to become autoantigens (Chapter 51). The first is the concept of *molecular mimicry*. According to this idea, exposure to sufficient doses of a pathogen-derived epitope that cross-reacts with a previously ignored or *cryptic* self-epitope can break self-tolerance to that epitope. A newer concept in autoantigenicity can explain why many autoantigens are proteins normally found intracellularly, where they are involved in nucleic acid and protein metabolism. These include small nuclear riboproteins, histones and heat-shock proteins. This involves the observation (discussed earlier with regard to cross-presentation) that apoptotic bodies are efficiently recognized by dendritic cells, and that many intranuclear and intracellular antigens are exposed on the extraverted surfaces of apoptotic bodies. Thus it is possible that, by inducing apoptosis, certain predisposing infections may elicit autoimmune reactions to cryptic self-epitopes.

Finally, tumor-specific and tumor-associated antigens are typically self-proteins.³³ In rare human cases, such as a peptide derived from papilloma virus type 16, they can be encoded by tumor viruses. Some tumor antigens, such as carcinoembryonic antigen (CEA), prostate-specific antigen (PSA), or the MAGE proteins of melanomas, are normal proteins that are merely overexpressed by tumor cells. These can serve as diagnostic

CLINICAL RELEVANCE

- >> The tautological and complementary interactions of antigens and their antigen receptors constitute the recognitive mechanism for both acquired immunity to pathogens and tumors, and autoimmunity towards the 'self'.
- >> Human genetic defects in antigen processing pathways result in three types of bare lymphocyte syndrome (BLS).
- >> Structural features of certain antigens may predispose them to induction of allergic (IgE) responses by affecting antigen processing.
- >> *Molecular mimicry* and exposure of cryptic self-epitopes are mechanisms leading to autoimmunity.
- >> Tumor-specific neoantigens can be detected by the immune system, often leading to selection for tumor variants lacking the relevant MHC and/or antigen-processing functions.

Tumor antigens are typically self-proteins that can be:

- Products of tumor viruses
- Over-expressed normal proteins
- Mutated products of oncogenes
- Clonally expressed idiotypes of antigen receptors.

markers or as a target for tumor-selective immunity. The antigenic products of mutated tumor suppressor genes and other oncogenes, such as *HER2*, the retinoblastoma protein RB and the breast cancer-associated antigen BRAC, are also called *neoantigens* and are potentially more specific targets for immunotherapy. The neoantigens expressed by these tumors arise as chance mutations during the many steps of carcinogenesis. Finally, the immune system itself provides a unique category of neoantigens that can be targets of immunotherapy, the clonally distributed products of rearranged antigen receptor genes – idiotypes – expressed by malignancies such as myelomas.

Antigen-presenting cells and antigen presentation

José A. Villadangos, Louise J. Young

7

The body is constantly being exposed to a diverse array of infectious agents. The primary function of the immune system is to alert and protect against invading pathogens. The first line of defense falls to the innate immune system, which is essential for the control of many bacterial, protozoan, fungal, and metazoan infections (Chapter 3). The effector cells and molecules of the innate immune system (e.g. macrophages, complement) react against pathogen components, such as bacterial cell wall components, that are fundamentally distinct from those normally found in our bodies. The adaptive arm of the immune system is alerted by innate mechanisms to generate a more specific and durable response that can be tailored to each particular pathogen. Adaptive immunity relies on two major devices for antigen recognition. The first are the immunoglobulins, which are expressed on the surface of B cells and secreted as antibodies during the humoral immune response. Immunoglobulins recognize (bind) antigen motifs in their native conformation, and these are accessible to the extracellular medium. Thus immunoglobulins are very effective at binding and neutralizing soluble toxins, or at attaching to the surface of pathogens to tag them for destruction by macrophages or the complement system (Chapter 20). However, immunoglobulins are ineffective against pathogens capable of living within the cells, which include viruses and some bacteria (e.g. *Mycobacterium*) and protozoans (e.g. *Plasmodium*). Detection of intracellular pathogens relies on the second major recognition device of the adaptive immune system, the eponymous T-cell receptors (TCRs).

TCRs are expressed on the surface of T cells and are structurally similar to the immunoglobulins. However, unlike immunoglobulins, TCRs are used only for antigen recognition, never as secreted effector proteins (Chapter 4). Another major difference between immunoglobulins and the TCRs is that TCRs cannot recognize antigens in their native state, nor in isolation. The structural motifs recognized by individual TCRs consist of small peptide fragments derived from proteins belonging to the intracellular pathogen. Furthermore, these peptide antigens are not recognized in isolation, but only when bound to major histocompatibility complex (MHC) molecules expressed on the surface of infected cells (Chapter 5). This constitutes the structural basis of the phenomenon of *MHC restriction* whereby the T cells of an individual are selected to recognize only peptide antigens presented by the MHC *allotypes* of that

individual.¹ The process that leads to formation of MHC–peptide complexes for T-cell recognition is called *antigen presentation*.² This involves degradation of the antigen, which is normally referred to as *antigen processing* (Chapter 6). The term *antigen-presenting cell* (APC) is operative; it is used to refer to the cells that display MHC–peptide complexes during a particular immune response.

Some specialized cells of the immune system, termed *professional APC*, can use their MHC molecules not only to display antigens derived from pathogens that are infecting the cells themselves, but also to capture pathogens from the extracellular medium, or even other cells infected with pathogens. These professional APCs present the pathogen antigens on their own MHC molecules. Such cells can thus communicate with T cells specific for the pathogens via interactions between the MHC–peptide complexes and the TCR. This interaction plays a key role in immune protection, because a fully fledged immune response requires the

KEY CONCEPTS

NON-PROFESSIONAL AND PROFESSIONAL ANTIGEN-PRESENTING CELLS (APC)

- >>> All nucleated cells express major histocompatibility complex (MHC) class I molecules and are *nonprofessional* APCs
- >>> *Professional* APC constitutively express MHC class II molecules and possess one or more mechanisms for antigen capture. Within the immune system, professional APC include dendritic cells, B cells, and macrophages
- >>> All professional APC employ the same basic machinery for antigen processing and presentation. However, professional APC can differ in the way they capture antigens, and in the way the molecular components of the machinery are expressed and interact with each other. These sometimes subtle differences enable subsets of APCs to engage in different specific functions

intervention of antigen-specific T cells. This requirement acts as a safety mechanism to minimize the likelihood of self-reactivity. Self-reactivity is minimized by depleting the T-cell repertoire of autoreactive cells during negative selection in the thymus. If a T cell becomes activated, this must be because it has encountered a foreign antigen. Antigen presentation thus serves a dual purpose. On the one hand, it is used by all cells to alert the immune system about the presence of intracellular parasites; on the other hand, it allows professional APC to survey large tracts of the body and inform T cells about the presence of infections.

■ NON-PROFESSIONAL AND PROFESSIONAL ANTIGEN-PRESENTING CELLS ■

The term APC can be confusing, as it is sometimes used to refer to a particular cell type, and at other times to refer to the cells presenting antigen in the context of a particular immune response. For instance, in the absence of infection, all cells express MHC class I molecules and can be considered APC. However, under normal circumstances the peptides they present are derived only from normal self molecules, and as such induce little, if any, immune response. During a pathogen infection the term APC is used to refer only to those cells that are actually presenting pathogen antigens. Similarly, during an autoimmune response APC will refer to the cells that present the autoantigen. Therefore what constitutes an “APC” depends on the context in which the term is used. Because most cells of the body express MHC class I molecules, they can serve as APC for endogenous antigens derived from pathogens should they become infected with viruses or intracytosolic bacteria. This ensures that any infected cell is recognized and eliminated by cytotoxic T lymphocytes (Chapters 25 and 27).

The expression of MHC II molecules is restricted to cells that possess mechanisms to endocytose antigens and to communicate with T cells. Such cells are termed *professional* APC. Although all professional APC share the same basic machinery for antigen presentation, they differ

markedly in their mechanisms of antigen capture and in the way they handle their MHC class II molecules. In the next sections we will describe the functional specializations of the antigen presentation functions of the three major representatives of professional APC: dendritic cells (DC), macrophages, and B lymphocytes (Table 7.1).

DENDRITIC CELLS

DC are present in nearly all tissues, as well as the blood and the lymphoid organs. However, they are relatively rare; for example, they only account for 2–3% of the non-red blood cells of the spleen and lymph nodes. Yet they were one of the earliest described cell types, even though at the time they were not recognized as components of the immune system.³ The German clinician Paul Langerhans was conducting histological studies of skin epidermis in 1868 when he described cells with long, stellate processes, which became known as *Langerhans cells*. He thought that these cells were nerve terminals, and it was not until the 1960s that Langerhans cells were recognized as components of the hematopoietic system. However, it would take another 20 years to discover that Langerhans cells are the skin representatives of a more widely distributed cell type of the immune system, namely the DC. This resulted from the convergence of studies of Langerhans cells with a different line of research initiated in 1973 by Steinman and Cohn, who used the term *dendritic cells* to describe cells with long processes (‘dendrites’) isolated first from the spleen and later also from the lymph nodes.⁴ DC began to attract particular attention when it was found that they were the most efficient, if not the only, type of APC capable of fully stimulating (‘*priming*’) naïve T cells.⁵ Indeed, naïve T cells do not become effector T cells if they only engage MHC–peptide complexes with their TCR (Chapter 13). Such interaction triggers a signaling cascade in the naïve T cell that is usually termed ‘*signal 1*.’ To become fully activated *effector* T cells capable of fighting infection, naïve T cells also require additional signals transmitted by a combination of surface receptors and soluble cytokines that are collectively known as ‘*signal 2*.’⁶ It turned out that DC were highly adept at providing naïve T cells with both signals 1 and 2.

When Langerhans cells were found also to be capable of priming naïve T cells, a relationship between DC and Langerhans cells was hypothesized.⁷

Table 7.1 Properties of professional antigen-presenting cells (APC)

	Dendritic cell	Macrophages	B cell
Antigen uptake	Phagocytosis, Macropinocytosis Receptor-mediated endocytosis	Phagocytosis Receptor-mediated endocytosis	Receptor-mediated endocytosis (surface immunoglobulin only)
Major histocompatibility complex (MHC) II expression	Constitutively expressed, high levels inducible upon activation	Low levels, induced by activation	Constitutively expressed, high levels inducible upon activation
Role of antigen presentation	Initiation of immune response (naïve T-cell activation)	Recruitment of helper T cells for induction of inflammation	Recruitment of helper T cells for antibody production
Location	Lymphoid tissue Connective tissue Epithelia	Lymphoid tissue Connective tissue	Lymphoid tissue

Dendritic cells, macrophages, and B cells are the three major representatives of professional APC. Although these cells share the same basic MHC class II antigen presentation machinery, they differ in their mechanisms of antigen capture, their regulation of expression of MHC class II molecules, and the role that antigen presentation plays in that cell.

This was confirmed when Langerhans cells were found to traffic from the epidermis via the lymphatic system to the local subcutaneous lymph nodes, where they appeared as DC.⁸ Parallel studies that tracked the origin of DC contained in the lymph nodes draining the liver, gut, or lungs also indicated that such DC immigrated from the corresponding peripheral tissue. This led to the realization that Langerhans cells were in fact the skin epidermis representative of a wider network of DC distributed throughout the body.⁵ Now we know that this network is not constituted by a single type of cell, but comprises several DC subtypes that emerge from closely related, but separate, lines of development.⁹ Furthermore, the tissue localization, lifecycle and function of the DC subtypes differ, conferring on each subtype unique properties tailored to fight specific types of infection. We next describe the archetypical lifecycle of DC, commonly referred to as the ‘Langerhans cell paradigm,’ before delineating in more detail how the different DC subtypes fit or diverge from this paradigm.

The Langerhans cell paradigm of DC lifecycle and function

In peripheral tissues, Langerhans cells/DC form a network of interconnected cells with long, dynamic processes projecting into the extracellular spaces between the parenchymal cells (Figure 7.1). The resulting mesh provides a barrier that can easily detect any invading pathogen. DC do not passively wait to encounter pathogens in the tissues. In their so-called ‘immature’ state, they appear to be dedicated to sampling their

surroundings. For example, immature DC are highly active at all forms of endocytosis.¹⁰ They constitutively macropinocytose, an activity that in other highly endocytic cells such as macrophages (see below) is inducible, not constitutive. Macropinocytosis enables DC to engulf the equivalent of their own volume every hour, an impressive figure that highlights the role of DC in immunosurveillance. Immature DC are also phagocytic, an activity they use to capture bacteria, cellular fragments and even whole dying cells. Finally, they express a large array of surface receptors that they use to detect the particulate matter that has to be phagocytosed. These receptors also permit the DC to engulf soluble extracellular compounds such as immunocomplexes and glycoproteins.

A crucial feature of immature DC is their ability to detect pathogens. They express Toll-like receptors¹¹ and C-type lectins,¹² both of which recognize pathogen-associated molecular patterns such as components of the bacterial wall (lipopolysaccharide), or nucleic acid motifs typically found in bacteria (e.g., CpG-rich DNA) or viruses (e.g., double-stranded RNA) (Chapter 3). Detection of these molecular cues triggers activation of the DC. Activation can also occur upon recognition of so-called inflammatory or ‘danger’ signals released by tissues damaged by invading pathogens (Figure 7.2).¹³

Activated DC leave the tissues, enter the lymphatic system, and migrate to the T-cell areas of the lymph nodes (Chapter 2). Simultaneously, the DC undergo a series of dramatic phenotypic changes that together are known as ‘maturation.’^{7,14} ‘Mature’ DC are no longer endocytic. However, they become highly effective at presenting the pathogen antigens captured in the

Fig. 7.1 Migratory dendritic cells (DC) in the skin. This micrograph of a mouse skin explant seen from above shows Langerhans cells (one type of migratory DC) in the epidermis. The mice have been genetically altered to express a fluorescent protein only in Langerhans cells. Note the ‘dendritic’ shape of the cells, which form an interconnected network ready to detect the presence of invading pathogens. The dark spaces between the cells are occupied by nonfluorescent cells and connective tissue. (Courtesy of Rhys Allan and Frank Carbone, University of Melbourne.)

Fig. 7.2 Lifecycle of migratory and lymphoid organ-resident dendritic cells (DC). Migratory DC (green) and resident DC (yellow) are distributed throughout peripheral tissues and the lymphoid organs, respectively, where they are dedicated to sampling their environment in their so-called ‘immature’ state. Upon detection of pathogen products or inflammatory signals in the tissues (lightning bolt), migratory DC travel to the draining lymph nodes via the lymphatics where they develop into mature DC. Resident DC can detect such signals within the lymphoid organs themselves and mature *in situ*.

periphery at the time of activation. This reflects both the high expression of MHC class I and class II molecules (Chapter 5) and the ability of the DC to ‘freeze’ on their surface a large representation of long-lived MHC class II–peptide complexes, which are generated shortly after pathogen encounter.¹⁵ This is an important feature found only in DC. The persistence of antigen is referred to as *antigenic memory*. This special ability allows DC to present to naïve T cells in the lymph node antigens that may have been encountered at a distant peripheral site, and gives the DC time to encounter a T cell specific for that antigen.

Another special ability found primarily in DC is the capacity to present on their MHC class I molecules peptides derived from antigens synthesized by other cells (exogenous), a mechanism known as *cross-presentation* (Chapter 6). Most cells only load their MHC class I molecules with peptides derived from antigens they have themselves synthesized (endogenous), enabling their detection by cytotoxic T lymphocytes (CTL) if they become cancer cells or are infected with viruses (Chapter 18). The problem is that CTL derive from primed naïve CD8 T cells. Since DC are the only APC that can prime naïve T cells, if they were not able to cross-present they would have to express the tumor antigens, or be infected with viruses, in order to initiate responses against these challenges. However, many viruses avoid infecting DC or inactivate the antigen-presenting machinery of infected cells, and by definition tumor antigens are only expressed (or expressed in significant amounts) by transformed cells. Cross-presentation by DC thus probably plays a major – albeit still controversial – role in immunity against viruses and cancer.¹⁶

Another major feature of mature DC is their acquisition of high expression levels of B7 family members and other co-stimulatory molecules that provide the ‘signal 2’ required to activate naïve T cells.⁶ They also express high levels of CD40 which, upon engagement of CD40 ligand on activated CD4 T cells, “licenses” the DC to convert naïve CD8 T cells into effector CTL.¹⁷ Finally, mature DC secrete cytokines that promote the differentiation of naïve CD4 T lymphocytes into Th1-, Th2-, and perhaps other types of helper T cells, each of which produces a distinct cytokine production profile. The specific mechanisms employed by DC to dictate which differentiation program will be followed by the CD4 T cells, which are often referred to as ‘signal 3’, are still poorly understood.¹⁸ DC secretion of IL-12 plays a major role in promoting Th1 differentiation, but the molecules involved in Th2 or other types of differentiation programs are less well characterized. It is believed that the type of signal 3 delivered by the mature DC may be determined by the specific compound that caused its activation when immature. In this scenario, the DC would be able to ‘memorize’ the type of pathogen it encountered in the periphery and promote in the lymph node the type of Th cell differentiation best suited to fight that particular pathogen.

The finding that DC migration to the lymph node is coupled to their maturation into cells capable of activating naïve T lymphocytes has had a major impact because it provides an elegant solution to a problem that had puzzled immunologists for years. Naïve T cells do not enter peripheral tissues, circulating instead amongst the secondary lymphoid organs (spleen and lymph nodes) via the circulatory and lymphatic systems (Chapter 2). How can they then detect infections restricted to a peripheral site such as the skin? DC solve this problem by acting as antigen middlemen, capturing infectious agents in peripheral tissues and transporting them into the lymph nodes for presentation to the naïve T cells. Each lymph node is therefore a communication hub where T cells can be exposed to a representation

of the antigenic material contained in the peripheral tissues in the form of MHC–peptide complexes exposed on the surface of the DC.

Departures from the paradigm: dendritic cell subtypes and their specializations

Even as the lifecycle of Langerhans cells was being characterized, studies of the development and phenotype of DC purified from lymphoid organs indicated that not all DC responded to the paradigm typified by Langerhans cells. It is now well established that DC can be subdivided into several subtypes that differ in developmental origin, anatomical localization, lifecycle, and functional properties.¹⁹ Due to this heterogeneity, defining what constitutes a DC has become increasingly difficult. It is currently based on a combination of phenotypic and functional characteristics rather than on a single feature. These are: (1) the expression of the integrin CD11c; (2) the ability to endocytose antigens; (3) high expression of MHC class II and T-cell co-stimulatory molecules; and (4) the ability to activate naïve T cells. DC heterogeneity has been extensively characterized in mice and less so in humans. In fact, as we will point out later, the human equivalents of some of the known murine DC types have not yet been identified. Nevertheless, given the similarity between the immune systems of the two species, it is generally assumed that those equivalents do exist. We will now describe the major DC subtypes in the mouse system. Rather than providing an extensive list of the surface markers and functional features that characterize each subtype, we will focus on the major properties that distinguish them from each other.

KEY CONCEPTS

DENDRITIC CELL (DC) POPULATIONS

- >> DC can be *conventional* or *plasmacytoid*
- >> Among conventional DC, some subtypes first appear in peripheral tissues as *immature* DC. Upon encountering antigen, they migrate to the local lymph node, where they then acquire a *mature* phenotype. These *migratory* DCs constitute one-half of lymph node DC and are absent from spleen
- >> The remaining lymph node DC, and all of the splenic and thymic DC, emerge in the lymphoid organs themselves. They spend their entire lifespan in an immature state unless they encounter pathogens. These are the *resident* DC types
- >> Migratory DC can be subdivided into two major populations: *interstitial* DC, which are present in all organs, and *Langerhans cells*, which are only found in the epidermis. Resident DC can be subdivided into at least three populations. All different DC types probably play distinct, albeit still ill-defined, roles
- >> In the absence of infection, DC induce tolerance. Upon pathogen detection they induce immunity. The rules governing whether DC will induce one or the other are still poorly understood

Plasmacytoid DC versus conventional DC

A major subdivision of DC can be made between *plasmacytoid DC* and *conventional DC*. The defining property of plasmacytoid DC is that upon activation they release large amounts of type I interferons, which play important roles in immunity against viruses.²⁰ Plasmacytoid DC were originally described as *interferon-producing cells*. They contain large amounts of endoplasmic reticulum, befitting their role as producers of a secreted cytokine. It is this ultrastructural feature, similar to that observed in antibody-producing plasma cells, that gives plasmacytoid DC their name. Although DC belonging to this subtype express MHC class II and T-cell co-stimulatory molecules, and can stimulate naïve T cells, their antigen-capturing abilities remain controversial. Moreover, their capacity to present antigens appears rather poor compared to that of conventional DC.²⁰ Plasmacytoid DC are found in all lymphoid organs. They are also present in the blood because they recirculate among lymphoid organs, much like lymphocytes, without entering non-inflamed peripheral tissues. This is also in contrast with conventional DC, which generally do not exit lymphoid organs and simply die there. Together, these features place plasmacytoid DC as quite separate from the conventional DC. Indeed some authors have questioned the categorization of plasmacytoid DC as part of the DC lineage.²⁰ In the rest of this chapter we will use the term DC to refer exclusively to the conventional ones.

Migratory versus resident DC

Analysis of DC contained in mouse lymph nodes has revealed two major groups of DC. The first can be tracked back to an origin in the peripheral tissue drained by that lymph node, for example, the skin, the airways, and the gut for the subcutaneous, mediastinal, and mesenteric lymph nodes, respectively. Thus, if a fluorescent tracker is applied to those tissues, DC labeled with the tracker accumulate in the corresponding lymph node after a few hours. These are the *migratory* DC types.¹⁹ The migratory DC develop from earlier precursors that either multiply in the peripheral tissues themselves, or traffic from the bone marrow. The newly generated DC then stay in the tissue in an immature state until they receive the signals that trigger their migration and maturation, as described above. The migratory DC contained in most tissues appear homogeneous, so they probably represent a single population that is known as *interstitial DC*.

The DC migrating from the skin can be further subdivided into interstitial DC that migrate from the dermis (for this reason they are normally called *dermal DC*) and the classic Langerhans cells that migrate from the epidermis. The latter can be distinguished from the interstitial (dermal) DC by their expression of a unique antigen receptor called *langerin* and by their possession of *Birbeck granules*, an enigmatic racket-shaped intracellular organelle of as yet unknown function.³ The skin appears to be the only tissue that contains two distinct types of migratory DC, suggesting that immunosurveillance of the epidermis requires a dedicated type of DC (the Langerhans cells). The reasons behind this need for a specialized cell remain unclear. Thus, although Langerhans cells are usually described as the archetypical DC, they represent a rather restricted subtype dedicated to monitor the epidermis.¹⁹

Approximately half of the DC contained in the lymph nodes do not become labeled with the dyes used to track the migration of DC from peripheral tissues. These are the *resident* DC types. The resident DC are

the only types of DC contained in the spleen and the thymus. This would be expected since these organs are not connected with the lymphatic system and therefore cannot receive cells migrating from peripheral tissues via the lymph. Indeed, resident DC most likely develop in the lymphoid organs from earlier precursors that may continually migrate from the bone marrow or divide within the organs.²¹ The lifecycle of resident DC represents a clear departure from the 'Langerhans cells paradigm'.¹⁹ In the absence of blood infections, virtually all the resident DC display an immature phenotype analogous to that of the migratory DC contained in peripheral tissues. Most die without ever becoming mature. Their function there is probably to survey the blood. Although the blood is not usually mentioned as a 'peripheral tissue' susceptible to pathogen infection, it is the primary route of entry for the plethora of insect-borne microorganisms transmitted by blood-sucking insects. Some examples are the viruses that cause yellow fever or several forms of encephalitis, the bacterium *Borrelia burgdorferi*, which causes Lyme disease, and the malaria parasite *Plasmodium* spp. When the resident DC encounter pathogen-associated compounds carried in the blood, they become activated, undergo maturation, and present the pathogen antigens. Thus, the lymphoid organs and the blood can be considered the 'peripheral tissue' surveyed by the resident DC of the spleen and lymph nodes.¹⁹

The migratory and resident DC differ not only in location and lifecycle but also in their antigen presentation capacities and the type of Th response that they promote. Resident DC can also be further subdivided into three smaller populations (CD4⁺ DC, CD8⁺ DC and CD4-CD8⁻ DC), each of which plays its own distinct role in the immune response. For example, CD8⁺ DC are particularly efficient at capturing dead cells, cross-presenting antigens, and secreting IL-12 for the induction of Th1-type responses.¹⁶ The resident DC of the thymus also deserve special mention because their main function is not to survey the blood but to mediate negative selection of thymocytes²² (see below). Characterizing the functional specializations of each DC subtype and the molecular basis of their differences is an important goal of current DC research. This may allow the design of more effective immunotherapies tailored to specific outcomes.

Blood DC

Mouse blood DC have been difficult to analyze due to the obvious scarcity of starting material for cell purification. However, the blood is the preferred source for studies of human DC, so this is the tissue that has allowed the clearest comparison between the DC of the two species (see below). Mouse blood contains plasmacytoid DC and conventional DC, but conventional DC do not resemble any of the migratory or resident DC types described in the lymphoid organs. They do not appear to be their precursors either. The function and lifecycle of blood DC thus remain enigmatic.¹⁹

Monocyte-derived DC

Monocytes circulate through the blood and are best known as precursors of macrophages in tissues. However, they can also differentiate into DC, although it remains unclear what type of DC they generate. These do not appear to be any of the resident DC. Some reports have suggested that monocytes can differentiate into migratory DC,²³ but this may only happen in inflamed tissues. A current view holds that under

normal conditions migratory DC are continually renewed by non-monocyte precursors. During inflammation, however, the monocytes represent an 'emergency' source of new migratory DC.²¹ It remains unclear to what extent the newly generated monocyte-derived DC resemble the migratory DC that are normally produced in the absence of infection.

Human DC subtypes

If the preferred source for study of mouse DC has been the lymphoid organs, the blood has served as the preferred source for the study of human DC. These differences in origin have complicated efforts to establish phenotypic and functional correlations between human and murine DC subsets. However, when DC are isolated from homologous tissues, parallelisms become evident.⁹ Thus, human blood, like mouse blood, contains two major subsets of DC: plasmacytoid DC (CD1d⁺ IL3 receptor⁺) and conventional DC (CD1d⁺ IL3 receptor⁻). The terms *lymphoid* and *myeloid* are commonly used to refer to human plasmacytoid and conventional DC because it was once thought that each subset emerged from the lymphoid and myeloid hematopoietic lineages, respectively. Later studies have shown that this is not the case, so the two terms have become obsolete and should be avoided. Human blood is also the major source for monocytes that can be transformed into DC in culture (see below). The DC of human lymphoid organs remain poorly characterized. It is clear that both plasmacytoid and conventional DC are present, but the only human equivalent of a particular mouse lymphoid organ DC subtype described so far are the Langerhans cells. The equivalents of the interstitial and of the three resident DC subtypes described above remain unknown. This represents an important knowledge gap that limits the ability to translate to the clinic the findings of basic DC research conducted in the mouse system.

Generation of DC in culture

Studies of DC were marred for over 30 years due to their scarcity, the difficulty of the protocols required for their purification, and the lack of unique phenotypic markers to distinguish them from other hematopoietic cells. The fact that DC purified from tissues proved to be remarkably 'unstable' further compounded these technical difficulties. This is because Langerhans cells extracted from the epidermis, or resident DC purified from the spleen, undergo spontaneous maturation when put in culture, hampering the analysis of their 'immature' properties. This situation changed with the establishment of methods to generate DC *in vitro* by culturing mouse bone marrow precursors or human blood monocytes in medium supplemented with the growth factor granulocyte-macrophage colony-stimulating factor.^{24,25} Such cultures yield large numbers of DC that maintain their immature state until stimulated by the addition of pathogen-associated compounds or inflammatory mediators. This has allowed detailed studies of the mechanisms involved in DC activation and their transformation from antigen-capturing immature DC into antigen-presenting mature DC.

Human monocyte-derived DC are the most commonly used DC type in immunotherapy. However, we still do not know how to generate the migratory and resident human DC types normally found in the lymphoid organs. Only recently have protocols been established for the generation of their mouse equivalents.²⁶ Since these DC subtypes have functional properties that may be absent from monocyte-derived DC, it would be important to develop methods to generate them in culture

because they might be more suitable for clinical applications than those derived from monocytes.

Dendritic cells and tolerance

Throughout this chapter we have described DC as initiators of immune responses. However, DC have another major role, the induction of T-cell tolerance. Elimination of autoreactive T cells occurs primarily in the thymus during the process of negative selection (Chapter 9), whereby thymocytes that react too strongly with self MHC-peptide complexes displayed on the surface of thymic APC are eliminated. The major APC of the thymus involved in this process are DC.²²

Many autoreactive T cells escape negative selection and enter the circulation, where they can elicit autoimmune responses if they are not held in check by some mechanism of peripheral tolerance. These mechanisms can induce abortive proliferation of the autoreactive cells, their entry into an anergic state, or their regulation by suppressor or regulatory T cells (Chapters 9 and 16). The APC in charge of presenting self antigen for the induction of peripheral tolerance are also DC. This is paradoxical. How can DC promote T-cell tolerance and also be the major initiators of immune responses? The answer to this question is still unclear, but the most likely explanation is that DC that present antigens without having received activation signals associated with pathogens are tolerogenic.²⁷ Since peripheral tolerance occurs in the secondary lymphoid organs, such DC might be plasmacytoid DC, resident DC that have not received maturation signals, or even migratory DC that have undergone maturation in response to a constitutive differentiation program rather than to pathogen encounter. The implication of this conclusion is that tolerogenic and immunogenic DC may differ in their expression of surface molecules or cytokines that define their ability to initiate immunity or tolerance. If true, this would imply that DC could potentially be used as immunotherapeutic agents for the induction of tolerance as well as for vaccination purposes. However, the differences that distinguish tolerogenic and immunogenic DC remain poorly characterized.

KEY CONCEPTS

THE ROLE OF THE B-CELL RECEPTOR (BCR) IN HUMORAL IMMUNITY

- >> Each B cell expresses a unique antigen receptor, the surface immunoglobulin (Ig), whose antigen specificity is the same as the antibody (Ab) it will produce upon differentiation into Ab-secreting cells
- >> Recognition of antigen by the BCR promotes B-cell activation and presentation of antigenic peptides via major histocompatibility complex (MHC) class II molecules to CD4⁺ helper T cells
- >> The BCR keeps capturing antigen, promoting continued recruitment of T-cell help, for as long as the antigen persists in the extracellular environment. It acts as a gauge that determines when the humoral immune response should stop

B LYMPHOCYTES

B lymphocytes (B cells) constitute the major population of lymphocytes of the immune system. Generated constitutively through life, naïve B cells exit the bone marrow after negative selection and circulate the body, repopulating both the blood and the follicles of the secondary lymphoid organs (Chapter 8).

Naïve B cells become stimulated upon recognition of antigen with their specific B-cell receptor (BCR), which consists of a membrane-attached form of immunoglobulin (mIg) associated with several accessory molecules (see below). Engagement of the BCR initiates a series of events that culminate in the differentiation of B cells into plasma cells, the antibody-secreting cells responsible for eliciting the humoral arm of the adaptive immune response (Chapter 8). The capacity of B cells to capture, process, and present antigens to T cells is a requisite for the initiation of these events.²⁸ The reason for this is that B cells need to present antigen to helper CD4 T cells, which upon recognition of the antigen respond by providing signals back to the B cells using surface molecules and secreted cytokines. These signals further stimulate the B cells to proliferate and differentiate into antibody-producing cells.

Why don't the B cells differentiate autonomously into antibody-producing cells? The requirement for T-cell help introduces an additional layer of control to prevent formation of autoantibodies by potentially autoreactive B cells which may have escaped negative selection, as these would still need to encounter autoreactive T cells that themselves avoided being purged from the T-cell repertoire. For this "double-safe" mechanism to work, two conditions must be met. First, B cells must only present antigens recognized with their BCR; and second, B cells specific for a given antigen should be able to receive help only from previously activated T cells specific for that same antigen. The antigen-presenting function of B cells thus differs from that of DC in three important aspects. First, it is focused on presentation of antigens recognized with the BCR; second, B cells do not generally activate naïve T cells, instead they interact with helper T cells previously recruited from the naïve T-cell pool by DC; and third, B cells present antigen to T cells 'for their own benefit' rather than to stimulate T cells which will then collaborate with third-party cells.

In this section we will describe the specializations of B cells that underpin their specific antigen-presenting function, with particular emphasis on the role of the BCR in antigen endocytosis and promotion of processing and presentation of BCR-internalized antigens. We will then integrate the antigen-presenting activity of B cells in the process that culminates in the initiation of humoral immunity.

The influence of B-cell localization on their role as APC

The clonal nature of the B-cell repertoire implies the same type of problem for antigen detection that we described above for T cells. Namely, very few cells amongst the vast B-cell repertoire express the right immunoglobulin specificity capable of recognizing a given antigen. Therefore it would be impractical for B cells to circulate throughout the tissues to monitor for the presence of their antigen. Instead, B cells circulate through the secondary lymphoid organs, concentrating in the follicles. Antigens carried in the blood or seeping from tissues via the efferent lymph reach these areas and can be readily recognized by

B cells. However, there must be many antigens that do not reach the follicles passively, so it has been hypothesized that DC can transport these antigens to the lymph nodes and, in addition to processing and presenting them to T cells, expose them on their surface in intact form for B-cell recognition.²⁹

The role of the B-cell receptor in antigen presentation

Unlike DC and macrophages, B cells are not phagocytic or macropinocytic, and do not express multiple types of antigen receptors. Their capacity to endocytose antigen is restricted almost exclusively to those captured through their cell surface receptor, the BCR. While this makes B cells less efficient than other APC at presenting most antigens, it also makes them the most focused. The BCR consists of an mIg, which provides the antigen recognition component to the receptor, noncovalently associated to an Igα:Igβ heterodimer (Chapter 4). This dimer provides the signaling module to the receptor, as it contains an immunoreceptor tyrosine-based activation (ITAM) motif required for signal transduction that upon antigen engagement triggers internalization of the receptor-antigen complex and initiates a signaling cascade leading to B-cell activation.²⁸ Ig-mediated endocytosis allows B cells to concentrate in their endosomal compartments minute amounts of antigen due to the high specificity of their mIg molecules. It is easy to imagine how this process operates on soluble antigens, but less so for antigens associated with cellular membranes. However, it has recently been demonstrated that B cells can indeed endocytose antigens 'ripped' from cell surfaces,³⁰ so BCR-mediated endocytosis can account for presentation of even cell-associated antigens without the need to invoke a phagocytic mechanism for antigen capture.

The signaling cascade ignited by the BCR upon antigen engagement induces changes in the endocytic route that facilitate the trafficking of BCR-antigen complexes to the compartments where antigens are degraded and MHC class II molecules acquire their peptide cargo. Concurrently, BCR signaling induces increased MHC class II synthesis and delivery to the same compartments.²⁸ Presentation of BCR-internalized antigen is also facilitated by the expression of H-2O/human leukocyte antigen (HLA)-DO.³¹ This is an MHC class II-like molecule that functions in B cells as an inhibitor of H-2DM/HLA-DM, the chaperone that facilitates the displacement of the CLIP peptide from the peptide-binding site of MHC class II molecules (Chapter 6). DO inhibits DM function, and therefore formation of peptide-receptive MHC class II molecules, in all but the most acidic late-endosomal compartments. This is advantageous because BCR-internalized antigens are difficult to degrade due their stable association with the Ig-binding site, so their processing requires their degradation in vesicles of a low pH. HLA-DO inhibition of HLA-DM in less acidic compartments preserves the peptide-binding site of the MHC class II molecules until they reach the acidic compartments, where the antigens can be processed.

B-cell activation also promotes migration towards the T-cell areas of the spleen and lymph nodes, facilitating their encounter with antigen-specific helper T cells at the margin of the lymphoid follicles.³² T-cell-dependent activation of B cells occurs both through the interaction of CD40 on B cells and its ligand CD154 on helper T cells, and through secretion of cytokines including IL-4 by the T cell. Both signals serve to promote and sustain activation initiated by BCR engagement.

This results in the formation of primary foci, which then lead to the establishment of germinal centers – the multicellular compound where the humoral response develops.³³

The duration of the humoral response is dictated by BCR-mediated antigen presentation.

In the germinal centers the B cells multiply, undergo isotype switching, and differentiate into antibody-producing cells.³³ The Ig-encoding regions of some of the progeny B cells undergo somatic hypermutations, resulting in generation of new Ig sequences of variable affinity for the antigen. Since the availability of helper T cells in the germinal center is limiting, these B cells compete with each other to receive proliferation and differentiation signals. Those with higher-affinity Ig are better able to capture antigen and present MHC class II–peptide complexes to the helper T cell, so they are selected for a new round of proliferation and differentiation. The efficiency of MHC class II presentation by B cells within the germinal center is thus proportional to the quality of their immunoglobulin and to the amount of antigen accessible to the BCR. This mechanism acts as a gauge for when to downregulate the humoral immune response upon the clearance of antigen. At this stage B cells can no longer present antigen to helper T cells and the humoral immune response ceases.

MACROPHAGES

Widely identified as a scavenger cell, the loose definition of a macrophage is a large mononuclear cell with a high capacity for phagocytosis. Macrophages are distributed throughout the organs and differentiate from blood monocytes upon entering the peripheral tissues (Chapter 21). Depending on their specific location within the body, macrophages are adapted to play multiple roles, resulting in their adoption of different morphologies. Consequently, they are identified by individual names, such as the Kupffer cells that line the hepatic sinusoids of the liver, the alveolar macrophage of the lung, the osteoclasts found in bones, or the marginal-zone macrophages found within the pulp of the spleen and the lining of the circular and medullary sinuses of the lymph nodes. The wide distribution and heterogeneity of macrophages reflect the multiple roles they play, many of which are unrelated to immunity. For example, they are the cells in charge of engulfing and digesting cells that have reached the end of their lifecycle, and osteoclasts play an important role in bone remodeling.

During an infection, macrophages provide the first line of defense of the innate immune response by engulfing infectious agents and destroying them (Chapters 3 and 21). Phagocytosis of these agents is triggered by recognition of carbohydrate and lipid structures on microbial surfaces by receptors such as the mannose receptor, the scavenger receptor, complement receptors, and several Toll-like receptors.³⁴ In addition to triggering phagocytosis, these receptors signal macrophage activation, promoting antigen presentation, expression of T-cell co-stimulatory molecules, and the secretion of chemokines that attract helper T cells to sites of infection. The antigen-presenting ability of macrophages is relatively limited because their expression of MHC II molecules is not as high as in DC or B cells. Moreover, their endosomal proteolytic machinery is geared towards the destruction of endocytosed material rather than to the production of MHC ligands.³⁵ Nevertheless, they do present antigens to helper T cells arriving at sites of infection. The

interaction between the two cell types induces the macrophages to express anti-microbial mediators and proinflammatory cytokines that contribute to contain pathogen spread (Chapter 3).

CLINICAL IMPLICATIONS

The events that lead to the display of MHC–peptide complexes on the surface of professional APC can be seen as the initial stages of T-cell-dependent immune responses. These events are modulated by signals delivered by innate receptors of microbial products. The characterization of the machinery involved in antigen detection, uptake, processing, and presentation, and of the functional abilities of distinct APC has practical applications for the clinical application of immunology. Considerable effort is currently being expended on finding ways to increase the efficiency of uptake, processing, and presentation of vaccine antigens (Chapter 94).

One major goal is to develop vaccine formulations that can be targeted to specific populations of APC, in particular DC, so that the dose of vaccine required to elicit a response can be kept to a minimum. For example, the antigen might be linked to antibodies specific for DC surface markers or to molecular motifs recognized by antigen receptors. Inclusion of the right pathogen products (adjuvants) or even molecular modulators of immune responses such as CD40 ligand would be predicted both to increase the efficacy of a vaccine and to promote the most effective type of T-cell response for the pathogen. A variation of this theme would be to generate vaccines against tumor antigens that might elicit immune responses against cancer cells (Chapter 94).

As we have described in this chapter, the professional APC also play key roles in the induction of tolerance. Thus, it should also be possible to design vaccines to suppress, rather than induce, immune responses. Such vaccines might be useful in the prevention or treatment of hypersensitivity (e.g. asthma: Chapter 40) or autoimmune disorders (e.g. type 1 diabetes: Chapter 70). The challenge is to understand what causes APC to initiate immunity or tolerance. Does this depend on the type of APC presenting the antigen? Or do the types of immune modulators that accompany the antigen determine the tolerogenic or immunogenic potential of a vaccine? The answers to these questions might open a future of novel vaccine formulations that exploit our knowledge of the abilities of distinct APC and their antigen-presenting functions to treat, as well as prevent, a large array of diseases.

The realization that antigen presentation is the result of complex molecular interactions has led to the development of drugs capable of enhancing or inhibiting the formation of MHC–peptide complexes. Such drugs might have immunomodulatory properties. For instance, protease inhibitors have been used in mice to impair the processing and presentation of autoantigens and model allergens and thus reduce autoimmunity and hypersensitivity, respectively.^{36,37} Developing strategies to target such drugs to particular populations of APC is another approach that may allow enhancement of the efficacy of vaccines or the prevention of autoimmunity or allergic reactions. There is still much to be learned about the functional specializations of distinct APC, but the potential benefits of such knowledge should encourage investigators to continue their studies of these fascinating components of the immune system.

B-cell development and differentiation

Claudia Berek, Andreas Radbruch,
Harry W. Schroeder Jr.

8

B lymphocytes arise from multipotent hematopoietic stem cells that successively populate the embryonic para-aortic splanchnopleura, the fetal liver, and then the bone marrow. Stem cell daughter cells give rise to lymphoid multipotent primed progenitors (LMPPs), which in turn can give rise to either myeloid or lymphoid cells.^{1,2} LMPPs then produce common lymphoid precursors (CLPs), which can generate T cells, B cells, natural killer (NK) cells, and a special subset of dendritic cells. Final B-cell differentiation requires the exposure of CLP daughter cells to specialized microenvironments such as those found in the fetal liver and the bone marrow. These two tissues are the primary B lymphoid organs. The shift from fetal liver to bone marrow begins in the middle of fetal life and ends just prior to birth. B cells continue to be produced in the bone marrow throughout the life of the individual, although the rate of production decreases with age.

An intact and functional B-cell antigen receptor (BCR) complex, which consists of membrane-bound immunoglobulin (mIg), the Ig α and Ig β co-receptors, and ancillary signal transduction components, must be present in order for the developing B cell to survive (Chapter 4). The composition of the BCR is subject to intense selection. In the primary organs, hazardous self-reactive BCRs, as well as nonfunctional ones, can be culled by altering the composition of the receptor (receptor editing), by cell anergy, or by apoptosis of the host cell. Survivors of this initial selection process are released into the blood and thence to the spleen, lymph nodes, and other secondary lymphoid tissues and organs where selection for specificity continues (Chapter 2).

B-cell differentiation (Fig. 8.1) is commonly presented as a linear process defined by the regulated expression of specific sets of transcription factors, immunoglobulin, and cell surface molecules. Given the central role of the BCR (Chapter 4), the initial developmental steps are classically defined by the status of the rearranging immunoglobulin loci. With the development of monoclonal antibody technology, analysis of cell surface markers such as CD10, CD19, CD20, CD21, CD24, CD34, and CD38 has facilitated definition of both early and late stages of development, especially in those cases where immunoglobulin cannot be used to distinguish between cell types (Table 8.1). Of these, CD19, a signal transduction molecule that is expressed throughout B-cell development up to, but not including, the

mature plasma cell stage,³ warrants special mention as the single best clinical marker for B-cell identity.

In practice, B-cell development is a more complex process than the simple linear pathway depicted in Figure 8.1. For example, pro-B cells typically derive from a common lymphoid progenitor, but they can also develop from a bipotent B/macrophage precursor. Thus, B-lineage subsets identified by one fractionation scheme may consist of mixtures of subsets identified by others. The complexity of the process continues to yield competing nomenclatures. Therefore, it behooves the practitioner to clarify the fractionation scheme used by the reference laboratory when comparing patient findings to the literature.

KEY CONCEPTS

B-CELL DEVELOPMENT IN THE PRIMARY LYMPHOID ORGANS

- >> Commitment to the B-cell lineage reflects differential activation of transcription factors that progressively lock the cell into the B-cell pathway
- >> B-cell development is typically viewed as a linear, stepwise process that is focused on the assembly and testing of immunoglobulin function, first in the fetal liver and bone marrow, and then in the periphery:

Failure to assemble a functional receptor leads to cell death

Expression of a functional receptor subjects the B cell to antigen selection

B cells with inappropriate specificities tend to be eliminated

B cells responding appropriately to external antigen may develop into either immunoglobulin-secreting plasma cells or into memory cells

At the clinical level, B-cell development can be monitored by examining the pattern of expression of lymphoid-specific surface proteins

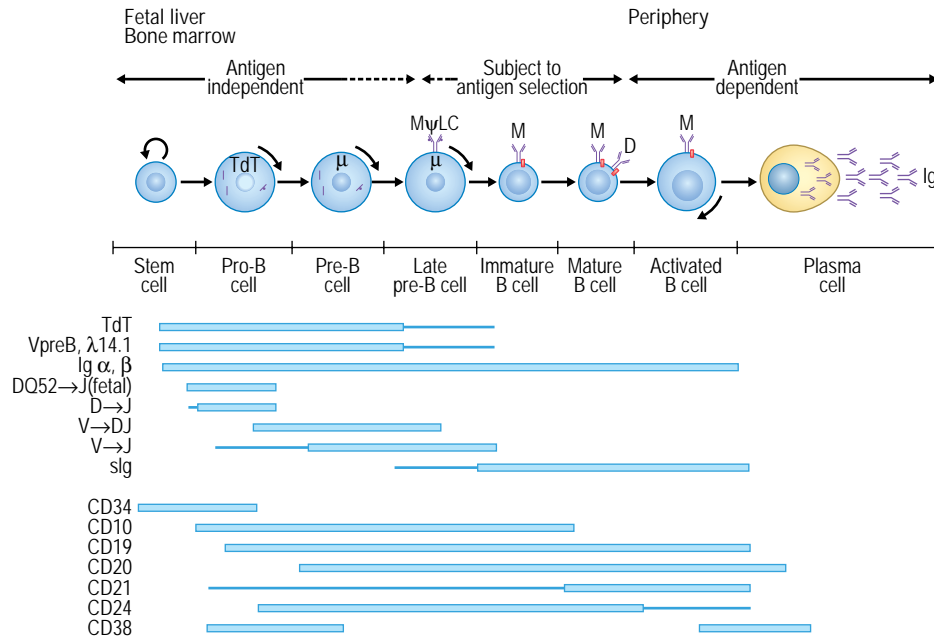

Fig. 8.1 Model of B-cell differentiation. B-cell development is typically viewed as a linear progression through different stages of differentiation: the various processes associated with the assembly of the B-cell antigen receptor complex and the expression pattern of surface molecules whose presence or absence are illustrated through use of bars. The various steps in immunoglobulin rearrangement and the pattern of expression of these surface molecules can be used to characterize stages in B-cell development.

Initial commitment to the B-cell lineage requires activation of a series of transcriptional and signal transduction pathways. At the nuclear level, the transcription factors PU.1, Ikaros, ID-1, E2A, EBF, and PAX-5 play major roles in committing progenitor cells to the B-cell lineage.⁴ However, after lineage commitment has been established, it is the composition of the BCR that controls further development.

Each B-cell progenitor has the potential to produce a large number of offspring. Some will develop into plasma or memory B cells, while others – the majority – will perish.⁵ Most of the defined steps in this process of development represent population bottlenecks: developmental checkpoints wherein the developing B cell is tested to make sure that its BCR will be beneficial. In the periphery, exposure to antigen is associated with class switching and hypermutation of the variable domains of the antigen receptor. A few select survivors earn long lives as part of a cadre of memory B cells. These veterans are charged with the responsibility to rapidly engage antigen to which they have been previously exposed, providing experienced protection against repeated assault.

Specialized microenvironments also play a role in peripheral B-cell development (Chapter 2), each of which enables the B cell to properly engage different types of antigens or venues of attack. In the marginal zone, mature splenic B cells lie in wait for bacterial pathogens. In the lymphoid follicles, B cells reactive with a given antigen collaborate with T cells and follicular dendritic cells (FDC) in order to maximize the immune response. In the germinal centers (GC), B cells use class switching and somatic mutation to modify and enhance the function and affinity of their immunoglobulins. And, underneath mucosal surfaces, B cells are primed to express IgA.

■ B-CELL DEVELOPMENT BEGINS IN THE PRIMARY LYMPHOID ORGANS ■

GENERATION OF A FUNCTIONING ANTIGEN RECEPTOR IS KEY TO THE VIABILITY OF A B CELL

Immunoglobulin rearrangement is hierarchical. In pro-B cells, D_H \rightarrow J_H joining precedes V_H \rightarrow DJ_H rearrangement (Chapter 4); and V_L \rightarrow J_L joining takes place at the late pre-B-cell stage.

Production of a properly functioning B-cell receptor is essential for development beyond the pre-B-cell stage. For example, function-loss mutations in RAG-1/2 and DNA-dependent protein kinase (DNA-PKcs, Ku 70/80) preclude B-cell development. For the pro-B cell the dismal reality is that only one of three possible splices will place the V_H and J_H in the same reading frame. The opportunity to try rearrangement on the second chromosome gives failing pro-B cells a second opportunity. Together, this provides the cell with five chances out of nine for initial survival ($\frac{1}{3} + \frac{1}{3} \times \frac{2}{3}$). In-frame, functional VDJ_H rearrangement allows the pro-B cell to produce μ H chains, most of which are retained in the endoplasmic reticulum. The appearance of cytoplasmic μ H chains defines the pre-B cell. Early pre-B cells are marked by their large size.

VpreB, and $\lambda 14.1$ [$\lambda 5$], which together form the surrogate light chain (ψ LC), and Ig α and Ig β are constitutively expressed by pro-B cells. Pre-B cells whose μ H chains can associate with surrogate light chains form a pre-B-cell receptor. Its appearance signals the termination of further H-chain rearrangement (*allelic exclusion*), which is followed by four to

Table 8.1 Cell surface proteins active in early B-cell development

Gene	Class or alternative name	Associated or targeted genes or molecules	B-cell developmental phenotype in human or mouse associated with disrupted function of the indicated gene
The B-cell receptor complex			
μ -chain	Immunoglobulin superfamily	κ , λ , L chains, Ψ L chain, CD79 a, b (Ig α , β)	<i>Arrest at pre-B-cell stage</i>
λ 14.1	Immunoglobulin superfamily	VpreB, μ H chain	<i>Arrest at pre-B-cell stage</i>
CD79a, b (Ig α , β)	Immunoglobulin superfamily, cytoplasmic ITAM motifs	H chain, LYN, FYN, BLK, SYK	<i>Arrest at pro-B-cell stage</i>
Other cell surface proteins			
CD10	Type II metalloproteinase	Hydrolyzes peptide hormones, cytokines	Not expressed in murine B-cell progenitors
CD19	Immunoglobulin superfamily	mIgM, PI-3 kinase, VAV, LYN?, FYN?	Panhypogammaglobulinemia, normal numbers of CD20+ B cells in the blood
CD20	Four transmembrane domain surface molecule	B-cell Ca ²⁺ channel subunit; indirectly interacts with LYN, FYN, LCK	<i>20–30% reduction in B-cell numbers</i>
CD21	Complement control protein	iC3b, C3dg, C3d, CD19, CD81, Leu 13, CD23	<i>Diminished T-cell-dependent immune responses, decreased germinal center formation, reductions in affinity maturation</i>
CD24	GPI-linked sialoglycoprotein	Ligand for P-selectin (CD62P)	<i>A57V polymorphism associated with increased risk of multiple sclerosis. Deletion in mice leads to reductions in late pre-B and immature B-cell populations</i>
CD34	Type I transmembrane glycoprotein	Ligand for L-selectin (CD62L) and E-selectin (CD62E)	Not expressed in murine B-cell progenitors
CD38	Type II transmembrane glycoprotein ADP-ribosyl cyclase, cyclic ADP-ribose hydroxylase	ADP ribosylates proteins	<i>Diminished T-cell-dependent immune responses, augmented responses to T-cell-independent type 2 polysaccharide antigens</i>

six cycles of cell division;⁶ a process associated with a progressive decrease in cell size. Late pre-B daughter cells reactivate RAG1 and RAG2 and begin to undergo $V_L \rightarrow J_L$ rearrangement. Successful production of a complete κ or λ light chain permits expression of conventional IgM on the cell surface (sIgM), which identifies the *immature* B cell. Immature cells expressing self-reactive IgM antibodies may undergo repeated rounds of light-chain rearrangement to lessen the self-specificity of the antibody, a process termed *receptor editing*.⁷

Immature B cells that have successfully produced an acceptable IgM B-cell receptor extend transcription of the H-chain locus to include the C δ exons downstream of C μ . Alternative splicing permits co-production of IgM and IgD. These now newly *mature* IgM+IgD+ B cells enter the blood and migrate to the periphery where they form the majority of the B-cell pool in the spleen and the other secondary

lymphoid organs. The IgM and IgD on individual cells share the same variable domains.

TYROSINE KINASES PLAY KEY ROLES IN B-CELL DEVELOPMENT

Signaling through the BCR is required for continued development. Bruton's tyrosine kinase is an important component of the phospholipase C γ (PLC γ) pathway, which is used in BCR signaling. Deficiency of BTK function results in the arrest of human B-cell development at the pre-B-cell stage⁸ and is the genetic basis of X-linked agammaglobulinemia (Chapter 34).

BLNK is a SRC homology 2 (SH2) domain-containing signal transduction adaptor. When phosphorylated by SYK, BLNK serves as a

scaffold for the assembly of cell activation targets that include GRB2, VAV, NCK, and PLC γ . An agammaglobulinemic patient lacking pre-B and mature B cells has been reported with a loss-of-function mutation in BLNK.⁹

FLT3 (FLK2) is a receptor tyrosine kinase belonging to the same family as c-FMS, the receptor for colony-stimulating factor-1 (CSF-1). FLT3 ligand, which has homology to CSF-1, is a potent co-stimulator of early pro-B cells. In mice, targeted disruption of *flt3* leads to a selective deficiency of primitive B-cell progenitors.

CELL SURFACE ANTIGENS ASSOCIATED WITH B-CELL DEVELOPMENT

B-cell development is associated with the expression of a cascade of surface proteins, each of which plays a key role in the fate of the cell (Fig. 8.1 and Table 8.1). The timing of the appearance of each of these proteins can be used to analyze further the process of B-cell development.

CD34 is a highly glycosylated type I transmembrane glycoprotein that binds to CD62L (L-selectin) and CD62E (E-selectin) and thus likely aids in cell trafficking (Chapter 12). It is expressed on a small population (1–4%) of bone marrow cells that includes hematopoietic stem cells. Minimal hematopoietic defects have been documented in mice made deficient for CD34. However, such observations must be viewed with caution when extrapolated to humans, because CD34 is not expressed on hematopoietic stem cells in the mouse.

CD10, also known as neprilysin, neutroendopeptidase, and the common acute lymphocytic leukemia antigen (CALLA), is a type II membrane glycoprotein metalloprotease. CD10 has a short N-terminal cytoplasmic tail, a signal peptide transmembrane domain, and an extracellular C-terminal domain that includes six N-linked glycosylation sites. The extracellular domain contains 12 cysteines whose disulfide bonds help stabilize its zinc-binding pentapeptide motif, which is involved in its zinc-dependent metalloprotease catalytic activity. By virtue of its protease activity, it is thought to downregulate cellular responses to peptide hormones and cytokines. Inhibition of CD10 activity on bone marrow stromal cells enhances B-cell maturation. CD10 (CALLA) is used as a marker for pre-B acute lymphocytic leukemias and for certain lymphomas. Although not expressed in mouse B cells, CD10 belongs to the same family and has activity that is similar to mouse BP-1.

CD19 is a cell surface glycoprotein of the immunoglobulin superfamily that is exclusively expressed throughout B-cell development from the pro-B-cell stage up to, but not including, the mature plasma cell stage (Fig. 8.1).³ CD19 exists in a complex with CD21 (complement receptor 2: CDR2), CD81 (TAPA-1), and Leu 13. With the help of CD21, CD19 can bind the complement C3 cleavage product C3d. The simultaneous binding of sIgM and CD19 to a C3d-antigen complex enables CD19 and the BCR to interact and thereby provides a link between innate and adaptive immune responses (Chapter 3). CD19-BCR interactions permit the cell to reduce the number of antigen receptors that need to be stimulated in order to activate the cell. Co-activation also reduces the threshold required for B-cell proliferation in response to a given antigen.

The cytoplasmic domain of CD19 contains nine conserved tyrosine residues which, when phosphorylated, allow CD19 to associate with PI-3 kinase and the tyrosine kinase VAV. Patients deficient in CD19 have normal numbers of CD20⁺ B cells in the blood, but are panhypogammaglobulinemic and are susceptible to sinopulmonary infections.¹⁰

CD20 contains four transmembrane domains and cytoplasmic C- and N-termini. It is a member of the CD20/Fc ϵ RI β superfamily of leukocyte surface antigens. Differential phosphorylation yields three forms of CD20 (33, 35, and 37 kDa). Activated B cells have increased fractions of the 35 and 37 kDa forms of the antigen. CD20 appears to function as a B-cell Ca²⁺ channel subunit and regulates cell cycle progression. It can interact directly with major histocompatibility complex (MHC) class I and II molecules, as well as members of another family of four transmembrane domain proteins known as the TM4SF: CD43, CD81, and CD82. It also appears to interact indirectly with LYN, FYN, and LCK. In mice, loss of CD20 function leads to a 20–30% reduction in B-cell numbers. B-cell development, tissue localization, proliferation, T-cell-dependent antibody responses, and affinity maturation are otherwise normal.

CD21 (complement receptor 2: CR2) is a cell surface protein that contains a small cytoplasmic domain and an extracellular domain consisting of a series of short consensus repeats termed complement control protein domains. These extracellular domains can bind three different products of complement C3 cleavage: iC3b, C3dg, and C3d. When binding these products, CD21 acts as the ligand-binding subunit for the CD19-CD21-CD81 complex, tying the innate immune system to the adaptive immune response.³ Mice that lack CD21 exhibit diminished T-dependent B-cell responses. However, serum IgM and IgG are in the normal range.

CD24 is a glycosphatidylinositol-linked sialoprotein that serves as a ligand for P-selectin (CD62P). It is expressed on progenitor, immature, and mature B cells. Its expression decreases in activated B cells and is lost entirely in plasma cells. Monoclonal antibodies against CD24 inhibit human B-cell differentiation into plasma cells. In mice, CD24 is also known as HSA, or heat-stable antigen. Mice made deficient for CD24 show a leaky block in B-cell development with a reduction in late pre-B and immature B-cell populations.¹¹ However, peripheral B-cell numbers are normal and no impairment of immune function has been demonstrated.

CD38 is a bifunctional enzyme that can synthesize cyclic ADP-ribose (cADPR) from nicotinamide adenine dinucleotide (NAD⁺) and also hydrolyze cADPR to ADP-ribose. It is presumed that the enzyme exists to ADP-ribosylate target molecules. CD38 is expressed on pre-B cells, activated B cells, and early plasma cells, but not on immature or mature B cells or on mature plasma cells. Antibodies to CD38 can inhibit B lymphopoiesis, induce B-cell proliferation, and protect B cells from apoptosis. CD38 knockout mice exhibit marked deficiencies in antibody responses to T-cell-dependent protein antigens and augmented antibody responses to T-cell-independent type 2 polysaccharide antigen.¹²

TRANSCRIPTION FACTORS CONTROL EARLY B-CELL DIFFERENTIATION

Ultimately, B-cell development is a function of differential gene expression. Deficiencies in the function of the transcription factors that regulate lymphoid-specific gene expression can thus be expected to result in abnormal B-cell development (Fig. 8.2 and Table 8.2).

PU.1 is an ETS family loop-helix-loop (winged helix) transcription factor. ETS proteins contain a structure that binds purine-rich DNA sequences. PU.1 appears to regulate a number of lymphoid-specific genes, including CD79a (Ig α), J chain, μ -chain, κ -chain, λ -chain, RAG1, and terminal deoxynucleotidyl transferase (TdT). ETS family members are relatively weak transcriptional activations and typically

Fig. 8.2 Changes in the function of genes involved in early B-cell development can reduce or prevent the production of B cells and immunoglobulin. The stage of development at which abnormal function of selected set of transcription factors, cytokines, chemokines, and signal transduction elements can influence B-cell development is illustrated. A Greek delta (Δ) or a dash (-) indicates a loss of function of the gene in question. An upward arrow (\uparrow) indicates an increase in the function of the gene in question.

require the presence of other factors in order to activate or repress their target genes, and PU.1 is no exception. PU.1 has been shown to cooperate with PIP (LSIRF, IRF4), c-JUN, and c-FOS. PU.1-deficient mice demonstrate defective generation of progenitors for monocytes, and granulocytes as well as B and T lymphocytes, indicating a role in the generation of MPPs as well as LMPPs. PIP-deficient mice lack GC in peripheral lymphoid organs and exhibit defects in B-cell activation.¹³

Ikaros and Aiolos belong to the same zinc finger transcription factor family. Both are expressed during lymphoid development, but Ikaros is expressed in stem cells and in mature lymphocytes, whereas Aiolos is only expressed after commitment to the B-cell lineage. Ikaros transcripts are subject to alternative splicing, generating several isoforms, each of which differs in its DNA-binding patterns, tendency to dimerize, and nuclear localization. Among the genes bound by Ikaros are TdT, $\lambda 14.1$ ($\lambda 5$), VpreB, and LCK. Ikaros-deficient mice lack B cells. Aiolos-deficient mice exhibit elevated levels of IgG and IgE. With age, these mice tend to develop autoantibodies and B-cell lymphomas.

The E2A locus encodes two basic helix-loop-helix transcription factors that represent two alternately spliced products, E12 and E47.¹⁴ Targets for E2A include RAG-1 and TdT, the enzyme responsible for N addition (Chapter 4). The functions of E12 and E47 appear to overlap. However, E47 appears to play a greater role in driving TdT and RAG-1, whereas E12 is a better activator of EBF and PAX5, and thus helps commit developing cells to the B-cell lineage. In mice with disruptions in the *E2A* gene, B-cell development is arrested at an extremely early stage, prior to the first transcription of RAG-1.

ID-1 has a helix-loop-helix domain, but lacks a DNA binding domain. Thus, it can function as a dominant negative factor, inhibiting the function of helix-loop-helix transcription factors, such as E2A. ID-1 is only expressed in pro-B cells. ID-1 transgenic mice have a

phenotype that is very similar to E2A knockout mice, suggesting that Id-1 can regulate E2A function.

EBF, or early B-cell factor, is a helix-loop-helix-like transcription factor. EBF is expressed at all stages of differentiation except plasma cells and in mice has been shown to be critical in the progression of B cells past the early pro-B-cell stage. The developmental block in B-cell differentiation is similar to that seen in E2A mutants, suggesting that these transcription factors act cooperatively and regulate a common set of genes.

PAX5 is a paired-box, or domain, transcription factor that, among the progeny of hematopoietic stem cells, is expressed exclusively in cells of the B-cell lineage. PAX5 has both a positive and a negative effect on B-cell differentiation. In mice, B-cell precursors require PAX5 in order to progress beyond the pro-B-cell stage. The presence of PAX5 also prevents early B-lineage progenitors from transiting into other hematopoietic pathways, including those leading to the development of granulocytes, dendritic cells, macrophages, osteoclasts, NK cells, and T cells.

MODULATION OF B-CELL DEVELOPMENT BY CHEMOKINES, CYTOKINES, AND HORMONES

Stromal cells can influence the microenvironment surrounding B-cell precursors through cytokines and chemokines, which exert local effects on B-cell development (Fig. 8.2). For example, CXCL12, which is also known as pre-B-cell growth-stimulating factor and as stromal cell-derived factor-1 (PDSF/SCF-1), promotes pro-B-cell proliferation. Mice with a targeted disruption of this gene exhibit impaired B lymphopoiesis in fetal liver and bone marrow, and fail to undergo bone marrow myelopoiesis.¹⁵ The mechanism by which CXCL12 regulates early B-cell development remains unclear. However, disruption of its

Table 8.2 Nuclear and cytoplasmic factors active in early B-cell development

Gene	Class or alternative name	Associated or targeted genes or molecules	B-cell developmental phenotype in human or mouse associated with disrupted function of the indicated gene
Transcription factors			
PU.1	Loop-helix-loop (winged helix)	CD79a (Ig α), μ H chain	Arrest prior to the pro-B cell stage
Ikaros	Zinc finger	RAG1, TdT, IL2R, VpreB, LCK	Arrest prior to the pro-B-cell stage
Aiolos	Zinc finger	RAG1, TdT, IL2R	Aging mice develop symptoms of systemic lupus erythematosus
E2A	Basic helix-loop-helix (BHLH)	RAG1, IgH, Ig κ , TdT, EBF, PAX5	Arrest prior to the pro-B-cell stage
EBF	EBF/Olf helix-loop-helix (HLH)-like	CD79a (Ig α), λ 14.1, VpreB, PAX5	Arrest prior to the pro-B-cell stage
PAX5	Paired-domain	CD19, λ 14.1, VpreB, BLK kinase, J chain, VH promoters, V κ promoters	Arrest at pro-B-cell stage
The recombinase complex			
RAG1, RAG2	Recombinase	Recombination signal sequences of immunoglobulin gene segments	Arrest at pro-B-cell stage
TdT	Nontemplated DNA polymerase	Coding ends of rearranging immunoglobulin gene segments	Absence of N nucleotides, diminished production of pathogenic anti-DNA autoantibodies in susceptible mice
DNA-PK	DNA repair complex	Multimeric complex consisting of DNA-PKcs, Ku70, Ku80 which repairs double-stranded DNA breaks	Arrest at pro-B-cell stage, original mouse SCID mutation identified as a loss of function mutation in DNA-PKcs
Protein tyrosine kinases			
FLK2/FLT3	Class III receptor tyrosine kinase	GRB2, SHC	Selective deficiency of primitive B-cell progenitors
BLNK	SH2 adapter protein	SYK, GRB2, VAV, NCK, Phospholipase C γ (PLC γ)	Arrest at pro-B-cell stage
BTK	BTK/TEC protein tyrosine kinase	Phospholipase C γ (PLC γ), SAB	X-linked agammaglobulinemia – arrest at pre-B-cell stage
SCID, severe combined immunodeficiency.			

receptor CXCR4 leads to failure in the homing of plasma cells to the bone marrow.

Interleukin-7 (IL-7) has a minimal proliferative effect on human B-cell progenitors and, unlike in the mouse, is not essential for B-lineage differentiation. Nevertheless, IL-7 enhances CD19 expression. IL-7 treatment of human pro-B cells also leads to a reduction in the expression of RAG-1, RAG-2, and TdT and thus can modulate the process of immunoglobulin gene segment rearrangement.

Interferons- α and β (IFN- α/β) are potent inhibitors of IL-7-induced growth of B-lineage cells in mice.¹⁶ The inhibition is mediated by apoptotic cell death. One potential source of IFN- α/β is bone marrow

macrophages. Another macrophage-derived cytokine, IL-1, can also act as a dose-dependent positive or negative modulator of B lymphopoiesis.

Systemic hormones also regulate lymphopoiesis.¹⁷ A role for sex steroids is suggested by the reduction in pre-B cells during pregnancy. Estradiol can also alter later stages of B-cell development, promoting expansion of the marginal-zone compartment. Prolactin appears to enhance production of both marginal-zone and follicular B cells. Mice with a loss of function mutation in the *Pit-1* transcription factor gene do not produce growth hormone, prolactin, or thyroid-stimulating hormone. These dwarf mice exhibit a defect in B-cell development that is correctable by the thyroid hormone thyroxine.¹⁸

KEY CONCEPTS

B-CELL DEVELOPMENT IN THE PERIPHERY

- >> T-independent activation of naïve B cells results in terminal differentiation into short-lived plasma cells or long-lived B1 cells
- >> T-dependent activation of B cells leads to germinal center formation, permitting somatic hypermutation and class switch recombination
- >> T-dependent activation of naïve B cells results in differentiation into memory B cells (via CD40/CD154 interaction) or short-lived plasma cells (via OX40/OX40-ligand)
- >> T-dependent activation of memory B cells results in expansion of memory B cells (via CD40/CD154) or differentiation into long-lived plasma cells (via CD27/CD70)
- >> Activated T cells control late B-cell differentiation by cell-bound ligands and secreted cytokines
- >> Activated B cells control T-cell development by presentation of antigen and co-stimulation

■ B-CELL DEVELOPMENT IN THE PERIPHERY: DIFFERENTIATION AND THE RESPONSE TO ANTIGEN ■

The lifespan of mature B cells expressing surface IgM and IgD appears entirely dependent on antigen selection. After leaving the bone marrow, unstimulated cells live for only a few days. Deletion of the transmembrane/intracellular domains of the B-cell antigen receptor of mature B cells disables their survival, which indicates that signaling through the BCR is essential for their survival. As originally postulated by Burnet's 'clonal selection' theory, B cells are rescued from apoptosis by their response to a cognate antigen.

The reaction to antigen leads to activation, which may then be followed by diversification. The nature of the activation process is critical. T-cell-independent stimulation of B cells induces differentiation into short-lived plasma cells with limited class switching. T-dependent stimulation adds additional layers of diversification, including somatic hypermutation (SHM) of the variable domains, which permits affinity maturation, class switching to the entire array of classes available (Chapter 4), and differentiation into the long-lived memory B-cell pool or into the long-lived plasma cell population.

BAFF AND APRIL CAN PLAY KEY ROLES IN THE DEVELOPMENT OF MATURE B CELLS

B cells leave the bone marrow while still undergoing initial maturation, demonstrating progressively higher levels of IgD expression with a commensurate lowering of IgM. They need the splenic environment in order to complete this maturation process. Immigrant splenic maturing B cells pass through two transitional stages, known as transitional stages 1 (T1) and 2 (T2). Only a minority of these cells will successfully make the transition, as this differentiation step is a crucial checkpoint for controlling self-reactivity.

Passage through this checkpoint requires the interaction of soluble B-cell-activating factor of the tumor necrosis family (BAFF), with its receptor, BAFF-R, which is primarily expressed on B cells.¹⁹ Death signals triggered through interaction of the BCR with self antigen may be counterbalanced by stimulation of BAFF-R, which enhances expression of survival factors such as Bcl-2 and at the same time downregulates proapoptotic factors.

BAFF and a second tumor necrosis factor (TNF) family member APRIL (a proliferation-inducing ligand) can also induce isotype switching in naïve human B cells.²⁰ APRIL, as well as BAFF, can bind to B-cell maturation antigen (BCMA) and transmembrane activator and calcium modulator and cyclophilin ligand interactor (TACI), both of which are members of the TNF-R family. BCMA is exclusively expressed on B cells, whereas TACI is expressed on B cells and activated T cells.

T-INDEPENDENT RESPONSES

Unlike T cells, which require presentation of antigen by other cells, B cells can respond directly to an antigen as long as that antigen is able to cross-link the antibodies on the B-cell surface. Such antigens, especially those that by nature cannot be recognized by T cells (e.g., DNA or polysaccharides) can induce a B-cell response independent of T-cell help. Depending on the cytokine milieu, the B cells may even class switch, although the range of available classes appears to be restricted. B cells that are activated by antigen alone do not take part in a GC reaction (see below).

T-DEPENDENT RESPONSES

Activated B cells express both MHC class I and class II molecules (Chapter 5) on their cell surface. They can thus present both intracellular and extracellular antigens to CD4 T helper and CD8 T cytotoxic lymphocytes. Their role as antigen-presenting cells is enhanced when they present peptides from the same antigen they have taken up with their antibodies (Chapter 7). Cognate recognition of the same antigen by both a B cell and a T cell permits each of these cells to activate the other reciprocally. In particular, T-cell-activated B cells express the co-stimulatory molecules CD80 and CD86, which in turn are required for activation of T cells via CD28 as well as their inactivation by CD152 (CTLA-4). Since B cells do not express IL-12, they do not induce expression of IFN- γ in the activated T cells but rather favor the differentiation of activated T cells into IL-4, IL-5, IL-10, and IL-13-expressing Th2 cells. These cytokines can support the CD40 induced expansion of memory B cells (IL-4), OX40 or CD27-induced differentiation into short-lived and long-lived plasma cells (IL-10), and CD40-induced class switch recombination (CSR) to IgG₄ or IgE (IL-4). Co-stimulation also permits T-helper cells to induce SHM, permitting affinity maturation.

■ ORGANIZATION OF THE PERIPHERAL LYMPHOID ORGANS ■

Compartmentalization in the immune system facilitates efficiency and regulation of the immune response. During development, the primary and secondary lymphoid organs are built up in an organized way.²¹ The process involves multiple factors that play various roles in the development, maintenance, and function of the lymphoid organs.

Fig. 8.3 T-cell and B-cell compartments within the white pulp of the spleen. Most splenic T cells can be found in a compartment that surrounds the central arterioles. This compartment is also referred to as the periarteriolar lymphocyte sheath (PALS). Most splenic B cells are found in two separate compartments – the marginal zone and the follicles. The marginal zone is located next to the marginal sinuses. The primary follicles are located within, but separate from, the T-cell zones. Within these primary follicles, B cells are embedded within a network of follicular dendritic cells (FDC).

B lymphocytes enter the secondary lymphoid organs through defined ways. Each organ exhibits a preferred route of entry.²² For example, most lymphocytes enter the spleen through the bloodstream whereas lymphocytes enter lymph nodes and Peyer's patches through high endothelial venules. In general, lymphocyte migration and the tissue-specific homing are strictly controlled by chemokines (Chapter 13). Dendritic cells, macrophages, and other highly specialized cells transport antigens from peripheral sites of entry into the secondary lymphoid organs. Within these organs, circulating lymphocytes survey available antigens. Binding to a cognate antigen activates the cell. Contact between a T cell and a B cell that have been activated by the same antigen permits initiation of a T-cell-dependent immune response.

THE SPLEEN

In the secondary lymphoid organs, T cells and B cells are segregated into clearly defined areas (Chapter 2). **Figure 8.3** illustrates the pattern observed in the white pulp of the spleen. It is in these areas where antigen-dependent B-cell activation occurs and where the cells subsequently undergo further differentiation. The marginal sinuses, the site of entry for lymphocytes, macrophages, and dendritic cells, separate the white pulp from the red pulp. These sinuses are lined with a mucosal addressin cell adhesion molecule-1 (MAdCAM-1) expressing endothelium (Chapter 12). In the marginal sinuses, one finds a specialized layer of metallophilic macrophages that are thought to control the entry of antigen into the white pulp.

FDC are highly specialized cells that present antigen to B cells (Chapter 7).²³ In contrast to other types of dendritic cells, FDC do not process antigen. Instead, FDC have abundant complement receptors and Ig Fc receptors that allow accumulation of antigen in the form of immune complexes within the B follicle. FDC are crucial for B-cell maintenance as well as for their activation and differentiation (see below).

Chemokines (Chapter 11) and cytokines (Chapter 10) play a major role in the organized development of the secondary lymphoid organs.²⁴ For example, mice deficient in the B-cell chemokine receptor CXCR5 fail to develop primary B-cell follicles in the spleen. In these mice, B cells enter the spleen through the marginal sinuses just as they do in their wild-type littermates. However, B cells in these CXCR5-deficient mice fail to move into the areas where B-cell zones would normally develop. Instead, a broad ring of B cells surrounds the T-cell zone.

The proinflammatory cytokine, TNF- α , and its receptor TNFR1 play an important role in the organogenesis of the spleen. In mice deficient for TNF- α , the marginal zones are expanded whereas the primary follicles are missing. The disruption of B-cell follicles in these mice is similar to the one observed in CXCR5-deficient mice. However, in contrast to the CXCR5-deficient mouse, no network of FDC develops.

Deficiency of lymphotoxin (LT α) has even more profound effects. This may be explained by the fact that the LT α exists in two forms, a soluble homotrimer that is released from the cell membrane after cleavage and interacts with the TNFR1 molecule and a membrane-bound heterotrimer LT α_1 /LT β_2 that interacts with the LT β receptor (LT β R). Thus, in mice deficient for LT α , both interactions are interrupted. The expression of LT α_1 /LT β_2 on B cells is crucial for the organized development of lymphoid structures and hence the induction of memory humoral immune responses. LT α_1 /LT β_2 -positive B cells by themselves are necessary and sufficient for the formation of the FDC network.

THE MARGINAL ZONE PROVIDES A HOME FOR B-CELL EARLY RESPONDERS

Mature B cells are not homogeneous. Functionally and developmentally distinct subsets exist. In the spleen, follicular B cells have a key role in the adaptive immune response, whereas marginal-zone B cells are

now seen as major players at the interface between the initial innate immune response and the delayed adaptive response.²⁵ The ability of marginal-zone B cells to respond rapidly to encapsulated bacteria by differentiating into antigen-specific plasma cells helps keep such infections under control. Marginal-zone B cells take time to develop and are not present in young infants. The marginal zone becomes fully populated only after the age of 2. In the physiologic absence of these marginal-zone cells, a poor response to bloodborne infections is commonly observed.²⁶

■ GERMINAL CENTERS ■

T-cell-dependent activation of follicular B cells can induce the formation of a GC, which is the microenvironment where affinity maturation of the humoral immune response takes place.²⁷ The interplay of hypermutation followed by antigen selection is the basis of affinity maturation. In the GC, B cells that express antibodies of high affinity are selected to develop into memory and long-living plasma cells.

GC develop only after T-cell-dependent activation of B cells. Their full function is dependent on the interaction between CD40 expressed on B cells and CD40L (CD154) expressed on activated T cells. Patients with loss of function mutations in CD40L have high serum levels of IgM and suffer from recurrent infections (hyper-IgM syndrome: Chapter 34).²⁸

In a primary immune response, it takes about a week for the complex GC structure to develop. In the spleen, a few days after activation of antigen-specific B cells and T cells, small clusters of proliferating B cells are observed at the border of the T-cell zone and the primary B-cell follicle.²⁹ The rapidly expanding B-cell clone seems to push the naïve B cells towards the edge of the primary follicle. The naïve B cells form a mantle zone around the newly developing GC and the primary follicle changes into a secondary follicle. Subsequently, the network of FDC becomes filled with proliferating, antigen-activated B cells. About the second week after immunization, the GC matures into a classical structure that contains a dark zone and a light zone. At this stage of GC development, proliferation is restricted to the dark zone. In the network of FDC, the B cells differentiate into plasma cells and memory cells. In the fully developed GC, dividing cells are termed centroblasts, whereas differentiating cells within the FDC network are termed centrocytes.

In the dark zone, proliferating B cells activate a mechanism of SHM.^{23,26} This is a highly specific process that is targeted towards the gene segments that encode the antigen-binding domain of the antibody molecule. Hypermutation introduces single nucleotide changes into the rearranged variable genes of the Ig molecules. By chance a few of these mutations result in a receptor with higher affinity for antigen. B cells expressing such receptors are favored for activation, particularly late in an immune response, when availability of antigen is limiting. Thus, within the dark zone, a clone of variants expressing antigen receptors with various affinities for the antigen is generated from a single B-cell progenitor. Antigen presented by the FDC is thought to select which B cells differentiate into memory cells or plasma cells. Only the few B cells with a high-affinity receptor for the antigen ultimately survive. The rest of the B-cell variants die by apoptosis, presumably due to the lack of sufficient stimulation through the B-cell antigen receptor complex.

■ THE MURINE B1 AND B2 PERIPHERAL B-CELL COMPARTMENTS (CD5 B CELLS) ■

Differential expression of the cell surface molecules IgD, CD5, CD11b/CD18, CD23, and CD45 allows the separation of the peripheral B-cell population into two compartments, B1 and B2.^{25,26,30} 'Conventional' B cells (B2 cells) express high levels of IgM and IgD, whereas 'CD5' B cells (B1 cells) express minimal surface IgD. B1 cells express little CD45 and virtually no CD23. They all express CD5 mRNA, although not all of them display CD5 on their cell surface. Based on the pattern of surface CD5 expression, B1 cells have been divided into B1a (CD5⁺) and B1b (CD5⁻) populations.

B1 cells seem to develop from distinct progenitors that represent a majority of B cells in fetal life.³³ Accordingly, in fetal liver all B cells are B1 cells, as are 40–60% of B cells in fetal spleen. Later in development, B1 cells comprise fewer than 10% of the splenic IgM⁺ B cells. In the peritoneal cavity B1 cells are abundant. In humans the subset of B1 B cells is not clearly defined.

Natural antibodies are found in every serum. These IgM antibodies are produced by B1 cells. They tend to have specificity for bacterial antigens as well as autoantigens. In general, they are both of low affinity and polyreactivity. However, these antibodies represent a second important and immediate defense against infectious organisms.

■ MOLECULAR MECHANISM OF SOMATIC HYPERMUTATION AND CLASS SWITCH RECOMBINATION ■

Immunoglobulin SHM and CSR are essential mechanisms for the generation of a high-affinity, adaptive humoral immune response. They allow the generation of effector plasma cells secreting high-affinity IgG, IgA, and IgE antibodies.

SOMATIC HYPERMUTATION

Hypermutation occurs only during a narrow window in B-cell development. The mechanism is induced during B-cell proliferation within the microenvironment of the GC.³²⁻³⁵ With a high rate of about 10^{-3} to 10^{-4} /basepair per generation, single nucleotide exchanges are introduced in a stepwise manner into the rearranged V-region and its 3' and 5' flanking sequences. Mutations are randomly introduced, although there is a preference for transitions (cytidine → thymidine or adenosine → guanine) over transversions. Analysis of the pattern of somatic mutations has revealed that the sequence of the complementarity-determining regions (CDRs: Chapter 4), the loops that form the antigen-binding site, have been selected to form mutation hot spots.

Effective hypermutation requires the V-gene promoter and transcription enhancer sequences. Indeed, the position of the V-gene promoter defines the start of the hypermutation domain, which spans 2000 nucleotides. Any heterologous sequence that is introduced into the V-gene segment locus will become a target of the hypermutation machinery. Thus, SHM can sometimes play a role in lymphomas and leukemias where oncogenes have been linked to Ig promoters and enhancers.

CLASS SWITCH RECOMBINATION

Upon transition from the immature to the mature state and leaving the bone marrow, the B cell starts to express IgD as well as IgM. Both IgM and IgD antibodies use the same V_HDJH -exon and promoter (Fig. 8.4). The molecular basis of co-expression of IgM and IgD by the same B cell is due to differential termination of transcription and splicing of the primary transcripts. Although sequences have been identified that are required for the control of termination and splicing of the $C\mu$ and $C\delta$ transcripts, none of the proteins involved is known. The role of IgD remains unclear. In mice, targeted inactivation of IgD has shown that IgD is not critical for B-cell activation and differentiation. IgD^{-/-} B cells show a slightly reduced capability for affinity maturation, but no other defect has yet been described.

Unlike IgD, the other antibody classes are not stably expressed together with IgM. B cells can switch from expression of their V_HDJ_H -exon with C_μ to expression of the same V_HDJ_H -exon with any of the downstream C_H genes (e.g., $C_{\alpha 1,2}$, $C_{\gamma 1,2,3,4}$, or C_ϵ ; Chapter 4). Class switching, like SHM, is a hallmark of B-cell activation. It can be induced by T-cell-independent signals (e.g., lipopolysaccharide) or by signals derived from T cells (e.g., CD40L). CD40L-deficient humans (X-linked hyper-IgM syndrome; Chapter 34) are severely impaired in the expression of Ig classes other than IgM.

TATA-less promoters located in front of the switch regions respond to signals from cytokines and B-cell activation-inducing ligands, like CD40L binding to CD40 on the B cell. Transcription starting from these promoters is essential in targeting switch recombination to the transcribed switch region. Such transcription starts with a small I-exon located between the promoter and the switch region, continues through the switch region itself, and finishes after including the entire C_H gene sequence.

The choice of C_H gene targeted for switch recombination in a particular B cell appears to be dependent on external cytokine signals, e.g., from T cells. IFN- γ targets CSR to IgG₂ in humans and IgG_{2a} in

mice, IL-4 to IgG₄ and IgE in humans and IgG₁ and IgE in mice, and transforming growth factor- β to IgA in both humans and mice. Other switch targeting cytokines have been described, although our knowledge is far from complete. It is evident, however, that those cytokines central for the organization of cellular, humoral, and mucosal immunity, respectively, recruit exactly those classes of antibodies that provide the most useful functions for their respective branches of the immune system.

BOTH SHM AND CSR REQUIRE ACTIVATION-INDUCED CYTIDINE DEAMINASE

Both molecular mechanisms, CSR and SHM, are dependent on an activation-induced cytidine deaminase (AID).^{34, 35} Mice deficient for this enzyme will express only IgM antibodies without somatic mutations, and patients with homozygous AID loss-of-function mutations present with a hyper-IgM syndrome (Chapter 34). The precise mechanism of action remains controversial, with first reports implicating AID as a potential RNA editing enzyme and subsequent reports pointing to single-strand DNA modifications. In either case, in SHM AID is targeted to the rearranged V-region gene that encodes the antigen-binding portion of the antibody molecule, and in CSR AID is targeted to the switch regions located upstream (5') of each C_H gene. Both processes, SHM and CSR, are dependent on transcription.

Hypermutation is proposed to occur in two steps.³⁵ The mechanism is induced by AID-catalyzed deamination of deoxycytidine (C) to deoxyuridine (U). The mispairing of U and deoxyguanosine (G) is then processed by uracil DNA glycosylase and targeted by repair pathways. As a consequence mutations at C-G pairs are observed. In the second step, mutations at A-T pairs are induced, probably during a mutagenic patch repair of U-G mismatches introduced by AID. A number of proteins, such as MSH2 and MSH6 (homologues 2 and 6 of the *Escherichia coli*

Fig. 8.4 Antibody class switch recombination. Recombination between switch regions (S_{μ} and S_{ϵ}) is preceded by transcription of these switch regions. Transcription is targeted by cytokines to distinct switch regions.

MutS), polymerase η or exonuclease-1 seemed to be involved; however, the mechanism is not yet clear.

Switch regions are composed of 1–6 kilobase-long GC-rich repetitive sequence motifs. G–C pairs within these motifs are targeted by AID. Deamination of C and processing by uracil DNA glycosylase creates an abasic site, which facilitates the introduction of double-strand DNA breaks. Joining and repair require the presence of DNA-phosphokinases, Ku70, Ku80, and probably other members of the general double-strand repair mechanism (Chapter 4).

Both mechanisms, SHM and CSR, have to be tightly controlled, since the introduction of double-strand breaks into the DNA not only poses a risk to the longevity of the B cell, but also permits translocations involving and activating oncogenes.³⁶ For example, for Burkitt lymphoma cells and for plasma cell-derived myeloma cells, the translocation and ectopic expression of the *c-MYC* gene are an apparent consequence of abnormal SHM and CSR.

■ B-CELL MEMORY ■

PLASMA CELLS

One of the key features of the immune system is immunological memory for antigens encountered in the past. Immunological memory of B lymphocytes is dependent on T-helper lymphocytes. While primary B-cell responses start with secreted low-affinity IgM antibodies after a lag-phase of 1–2 days and only gradually develop high-affinity antibodies of other classes, secondary responses start faster and with high-affinity antibodies of IgM and other classes. This protective humoral memory is provided by long-lived plasma cells.³⁷ These cells are generated in the secondary lymphoid organs and then migrate to the bone marrow or to a site affected by inflammation. In the bone marrow, they can survive for long periods without further activation and proliferating. By continuously secreting antibodies, long-lived plasma cells provide the individual with long-term humoral protection. If the original antigen recurs at higher concentrations, free antigen may activate memory B cells and induce again differentiation into high-affinity antibodies secreting effector plasma cells (Fig. 8.5).

Fig. 8.5 The two types of B-cell memory: reactive memory of memory B cells and protective memory of long-lived plasma cells. The relative concentrations of antibody and antigen over time are indicated.

MEMORY B CELLS

Memory B cells are derived from naïve B cells activated by antigen and T-cell help in extrafollicular or GC reactions. The differentiation to memory B cells is critically dependent on CD40 of the B cell and CD40L expressed by T cells and FDC.²⁸ Inactivation of the CD40 or CD40L genes by targeted mutation in the murine germline or by accidental mutation in humans leads to a hyper-IgM syndrome and a general lack of B-cell memory (Chapter 34). Interestingly, using CD27 as a marker for B-cell memory cells, a small fraction of IgM memory B cells have been detected in the peripheral blood of some patients with hyper-IgM syndrome. The pattern of cell surface antigen expression suggested that these cells are marginal-zone B cells. In humans, hypermutation is a mechanism that occurs during a narrow window of B-cell development in the GC. However, it seems possible that under certain circumstances the mechanism of hypermutation might be induced, when B cells are activated in a T-independent response, perhaps in the gut by signals delivered through Toll-like receptors.³⁸

■ DEVELOPMENT OF ECTOPIC LYMPHOID TISSUE IN AUTOIMMUNE DISEASE ■

In immune diseases such as myasthenia gravis, Sjögren's syndrome, Hashimoto's disease, or rheumatoid arthritis, ectopic lymphoid tissue may develop in the affected tissue or organ.^{39, 40} The presence of proinflammatory cytokines may support the development of additional lymphoid tissue.

The growth of ectopic lymphoid tissue in rheumatoid synovium offers an excellent example of this disease-related phenomenon. In healthy individuals, the synovium is made up by a thin lining layer of synoviocytes. In contrast, in patients with rheumatoid arthritis the diseased joint is highly

CLINICAL RELEVANCE

ABNORMAL B-CELL DEVELOPMENT AND DISEASES OF IMMUNE FUNCTION

- Failure to generate B cells or a normal repertoire of antibodies leads to humoral immune deficiency, which is commonly marked by recurrent sinopulmonary infections
- Failure to prevent the formation of antibodies with high avidity or high affinity to self-antigens can lead to autoimmune diseases
- The process of antibody repertoire diversification lends itself to the creation of mutations that can activate and modify oncogenes as well, leading to leukemia or lymphoma. Mechanisms include:

RAG1/2-catalyzed juxtaposition of an oncogene to an immunoglobulin promoter or enhancer, activating the oncogene

Activation-induced cytidine deaminase-induced somatic hypermutation of the oncogene, altering its function

infiltrated with varying numbers of T cells, B cells, plasma cells, macrophages, and dendritic cells. In the majority of patients, these mononuclear cells are loosely dispersed throughout the synovium. However, in some patients large, well-organized lymphocyte structures develop that are similar in appearance to the lymphoid follicles seen in the secondary lymphoid organs. At the center of these cell clusters one finds a network of FDC. Antigen presented by the FDC appears to activate the B cells, which induces proliferation. A layer of T cells, which may support B-cell differentiation into plasma cells, surrounds the central B cells. The analysis of the V-gene repertoire expressed in synovial B cells has demonstrated that during proliferation hypermutation is activated in a pattern similar to the one observed in normal secondary lymphoid organs. Thus, in rheumatoid arthritis a GC reaction can be induced within the synovial tissue. A central question is which antigens drive the immune response and select B cells to differentiate into memory and plasma cells. The ectopic lymphoid tissue may function as additional lymphoid tissue, in which case the immune response is no longer restricted to the peripheral lymphoid organs. Equally well, the ectopic lymphoid tissue may support a self-specific immune response. These questions remain active topics of investigation.

T-cell development

Ralph C. Budd, Karen A. Fortner

9

T-lymphocyte development must produce a large and diverse repertoire of functional T cells that can effectively combat a wide variety of infections without provoking a response against the host. The price for generating an increasingly varied population of antigen receptors needed to recognize a wide array of pathogens is the progressive risk of producing self-reactive lymphocytes that can manifest as an autoimmune disease, as well as other lymphocytes that make no fundamental interactions with major histocompatibility complex (MHC) molecules. The accumulation of either type of lymphocyte to critical numbers could be dangerous to the host. In order to minimize the possibility of retaining self-reactive T cells, or useless T cells that recognize no MHC-peptide complex, T lymphocytes are subjected to rigorous selection processes of positive and negative selection during development in the thymus. In addition, requiring two signals for activation prevents premature activation of T cells. Finally, the tremendous expansion of T cells that occurs during the response to an infection is resolved by the active induction of cell death. In perhaps no other organ are the processes of cell

proliferation and death more dynamically displayed than by lymphocytes during an immune response. Collectively, these processes severely restrict the possibility of clonal expansion occurring without strict control. The consequences of inefficient lymphocyte removal at any one of these junctures can be devastating to the health of the organism. This is vividly displayed in both humans and mice where naturally arising mutations in death receptors such as Fas result in massive accumulation of lymphocytes and autoimmune sequelae.

THE THYMUS

Development of T cells occurs within the microenvironment provided by the thymic epithelial stroma. The thymic anlage is formed from embryonic ectoderm and endoderm. The thymic epithelium develops from the third branchial cleft and the third and fourth pharyngeal pouches.¹ Once formed, this anlage is colonized by hematopoietic cells that give rise to dendritic cells, macrophages, and developing T cells.¹ As few as 50–100 bone marrow-derived stem cells enter the thymus daily. The hematopoietic and epithelial components combine to form two histologically defined compartments: the cortex, that contains immature thymocytes and the medulla, which contains mature thymocytes.

The cortex is the earliest apparent portion of the thymus. As stem cells begin to enter the thymus, two microenvironments emerge. The subcapsular cortex is composed of epithelial cells, including the thymic nurse cells, so named because they envelop groups of immature thymocytes. In fact, however, the term “nurse cells” is misleading, since the thymocytes that are enveloped are likely those chosen for apoptotic elimination. The cortex proper is a network of epithelial cells with ubiquitous processes that are in intimate contact with densely packed immature thymocytes, most of which express both CD4 and CD8 surface proteins that bind to MHC class II and class I molecules, respectively.

The medulla is composed of epithelial cells that are packed more tightly and are associated with thymocytes that bear exclusively the mature phenotypes of expressing only CD4 or CD8. There appears to be a mutually positive benefit of thymocyte-epithelial interaction in the

KEY CONCEPTS

THE THYMUS

- >> T cells develop in the thymus
- >> The thymus consists of three major regions: the cortex, the medulla, and the corticomedullary junction
- >> Most immature T cells, termed thymocytes, express both CD4 and CD8 and are found in the cortex
- >> The corticomedullary junction contains large numbers of macrophages and dendritic cells that arise from mesodermal tissue
- >> As thymocytes mature, they make their way through the corticomedullary junction to the medulla
- >> Mature thymocytes express either CD4 or CD8 and are found exclusively in the medulla

medulla, as the thymic medulla remains disorganized until populated by mature T cells.

The corticomedullary junction is more than just an interphase. It contains large numbers of macrophages and dendritic cells that arise not from ectoderm or endoderm, but from mesodermal tissue (especially the bone marrow).

The diversity of cell types that make up the thymic stroma is only beginning to be appreciated. Cortical epithelial cells, for example, appear to be largely responsible for positive selection of thymocytes. Dendritic cells, predominantly at the corticomedullary junction, are potent mediators of negative selection. Medullary epithelial cells may promote the maturation of thymocytes that have successfully passed the selection requirements.

The ability of different stromal components to regulate distinct developmental events is influenced in part by the particular surface molecules expressed and their density, as well as the stage of the developing thymocytes with which they interact. As an example, although all stromal cell types appear to express both MHC class I and class II molecules, macrophages and dendritic cells express particularly high levels of class II. As a result macrophages and dendritic cells are exceptionally efficient at antigen presentation compared to epithelial cells. Macrophages and dendritic cells also differ from epithelial cells in their expression of CD80/CD86, the ligands for the co-stimulatory molecule CD28. Thymic epithelial cells have also been shown to secrete granulocyte and granulocyte-macrophage colony-stimulating factors (G-CSF, GM-CSF), as well as interleukin-6 (IL-6) and IL-7, whereas dendritic cells are unusual in their secretion of IL-10 and IL-12.²

EARLY T-CELL DEVELOPMENT

T-CELL DEVELOPMENT WITHIN THE THYMUS

T cells must traverse two fundamental and stringent hurdles during their development into mature cells capable of mounting an immune response. First, a T cell must successfully rearrange the pair of genes that encode a heterodimeric T-cell receptor (TCR) (Chapter 4). Second, a T cell must survive thymic selection during which self-reactive T cells are eliminated. The survival rate of these two independent selection processes is less than 3%. These processes minimize the chances of autoreactive T cells escaping to the periphery.

The most common type of T-cell receptor, TCR- $\alpha\beta$, is an 80–90 kDa disulfide-linked heterodimer composed of a 48–54 kDa β -chain and a 37–42 kDa α -chain. An alternate TCR is composed of γ - and δ -chains. The TCR is noncovalently associated with as many as five invariant chains belonging to its associated signal-transducing CD3 complex. The structure of a TCR gene is very similar to that first described for immunoglobulin genes in B cells (Chapter 4). The combinatorial diversity generated by gene rearrangements within the two TCR chain loci plus the additional diversity generated by the introduction of nucleotides not encoded by the genome (N-region nucleotides) yield at least 10^8 theoretical possible TCR combinations. Mutations in the genes that engage in this rearrangement process can produce an arrest in lymphocyte development. For example, a mutation in a gene encoding a DNA-dependent protein kinase required for receptor gene recombination results in a severe combined immunodeficiency, a type of disorder that is typically identified by the acronym SCID (Chapter 35). TCR gene recombination thus

KEY CONCEPTS

T-CELL DEVELOPMENT IN THE THYMUS

- >> In order to reach the mature T-cell stage of development, T cells must successfully rearrange a pair of genes that encode a heterodimeric T-cell receptor (TCR) ($\alpha\beta$ or $\gamma\delta$) and survive thymic selection, during which self-reactive T cells are eliminated. Only 3% of thymocytes survive this process
- >> For the majority of T cells, the stages of T-cell development can be defined by the status of rearrangement and expression of TCR α and β , and the expression of CD4 and CD8, which proceeds CD4⁺CD8[−] → CD4⁺CD8⁺ → either CD4⁺CD8⁺ (cytotoxic T cells) or CD4⁺CD8[−] (helper T cells)
- >> TCR β rearrangement begins in CD4⁺CD8[−] cells; TCR α expression occurs in the CD4⁺CD8⁺ cells; thymocytes that are selected by class I go on to express CD8 alone; and thymocytes that are selected by class II go on to express CD4 alone
- >> Two types of selection occur in the thymus: positive selection, which requires the TCR on the cell surface to recognize either a MHC class I or class II molecule that is endogenous to the individual; and negative selection, which eliminates those T cells that bind too well to the endogenous MHC molecule and are thus in danger of becoming self-reactive

presents the first of the two major hurdles for developing lymphocytes. Since the developing T cell has two copies of each chromosome, there are two chances to rearrange each of the two TCR chains successfully. As soon as successful rearrangement occurs, further β -chain rearrangements on either the same or the other chromosome are suppressed, a process known as *allelic exclusion*. This limits the chance of dual TCR expression by an individual T cell. The high percentage of T cells that contain rearrangements of both β -chain genes attests to the inefficiency of this complex event. Rearrangement of the α -chain occurs later in thymic development in a similar fashion, although without apparent allelic exclusion.

Several other mutations have been identified that regulate early T-cell development and lead to a clinical SCID phenotype (Chapter 35). These include deficiencies in IL-7R α -chain, CD3 δ , CD3 ϵ , γ_c (X-linked SCID), CD45, JAK3, Artemis, RAG1 and RAG2, and adenosine deaminase.

The stages of thymocyte development can be defined by the status of rearrangement and expression of the two genes that encode the α - and β -chains of the TCR and the expression of CD4 and CD8. Thymocytes are divided into four main subsets based on their expression of CD4 and CD8: immature CD4⁺8[−] and CD4⁺8⁺, and mature CD4⁺8[−] or CD4⁺8⁺ cells (Fig. 9.1). During maturation, thymocytes proceed in an orderly fashion from CD4⁺8[−] → CD4⁺8⁺ → CD4⁺8[−] or CD4⁺8⁺. CD4 and CD8 define, respectively, the helper and cytolytic subsets of T cells (Chapters 17 and 18).

CD4⁺8[−] thymocytes can be further subdivided based on their expression of CD25 (the high-affinity IL-2 receptor α -chain) and CD44 (the hyaluronate receptor). Development proceeds in the

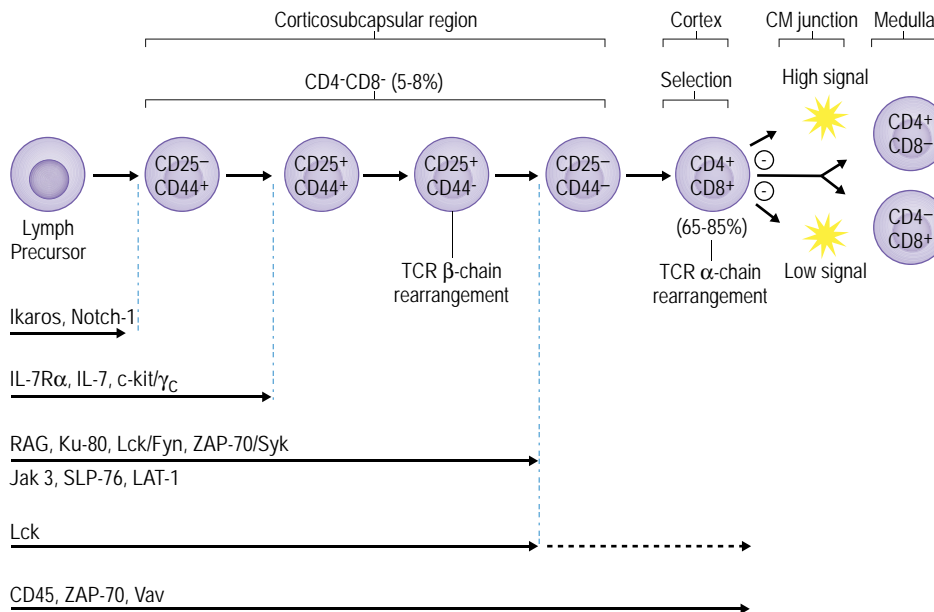

Fig. 9.1 Sequence of $\alpha\beta$ T-cell development in the thymus. The earliest thymocyte precursors lack expression of CD4 and CD8 ($CD4^-CD8^-$). These can be further divided into four subpopulations based on the sequential expression of CD25 and CD44. At the $CD25^+CD44^+$ stage, the TCR β -chain rearranges and associates with a surrogate α -chain known as pre-T α . Concomitant with a proliferative burst, thymocytes progress to the $CD4^+CD8^+$ stage, rearrange the TCR α -chain, and express a mature TCR complex. These cells then undergo thymic positive (+) and negative (-) selection. Thymocytes receiving a high-intensity or very low TCR signal are eliminated through apoptosis. The thymocytes that survive this rigorous selection process differentiate into mature $CD4^+$ or $CD8^+$ T cells. The extent of $\alpha\beta$ T-cell development in mice deficient for certain transcription factors, cytokines, and signaling molecules required for T-cell development is shown below. Headings at top indicate the region of the thymus populated by the various thymic subsets. The percentages indicate the proportion of each subset. C-M, corticomedullary.

order: $CD25^+CD44^+ \rightarrow CD25^+CD44^+ \rightarrow CD25^+CD44^- \rightarrow CD25^-CD44^-$. These subpopulations correspond to discrete stages of thymocyte differentiation. $CD25^-CD44^+$ cells express low levels of CD4 and their TCR genes are in germline configuration. These cells then down-regulate CD4 and upregulate CD25 to give rise to $CD25^+CD44^+$ thymocytes, which now express surface CD2 and low levels of CD3 ϵ . At the next stage ($CD25^+CD44^-$), there is a brief burst of proliferation followed by upregulation of the recombination-activating enzymes, RAG-1 and RAG-2, and the concomitant rearrangement of the genes of the TCR complex beginning with rearrangement of the TCR β -chain. A small subpopulation of T cells rearranges and expresses a second pair of TCR genes, known as γ and δ . Rearrangement in these cells begins with the γ -chain. These unusual $\gamma\delta$ T cells represent only 1–3% of peripheral blood T cells and are discussed below. Productive TCR β -chain rearrangement results in downregulation of RAG and a second proliferative burst. Loss of CD25 then yields $CD25^-CD44^-$ thymocytes.

The TCR β -chain cannot be stably expressed without an α -chain. Since the TCR α -chain has not yet rearranged, a surrogate invariant TCR pre- α -chain is disulfide linked to the β -chain.³ When associated with components of the CD3 complex, this allows a low-level surface expression of a pre-TCR and progression to the next developmental stage. Failure to rearrange the TCR β -chain successfully results in a developmental arrest at the transition from $CD25^+CD44^-$ to $CD25^-CD44^-$. This occurs in RAG-deficient mice as well as in *scid* mice and humans.

A number of molecules, including transcription factors, cytokines, and signaling molecules, are required for T-cell development (Fig. 9.1).¹ The IKAROS gene encodes a family of transcription factors required for the development of cells of lymphoid origin. NOTCH-1, a molecule known to regulate cell fate decisions, is also required at the earliest stage of T-cell lineage development. Cytokines including IL-7 promote the survival and expansion of the earliest thymocytes. In mice deficient for IL-7, its receptor components IL-7R α or γ_c , or the receptor-associated signaling molecule JAK3, thymocyte development is inhibited at the $CD25^+CD44^+$ stage. In humans, mutations in γ_c or Jak 3 result in the most frequent form of SCID. Pre-TCR signaling is required for the $CD25^+CD44^- \rightarrow CD25^-CD44^-$ transition. Thus, loss of signaling components including Lck, SLP-76, and LAT-1 results in a block at this stage of T-cell development. TCR signals are also required for differentiation of $CD4^+CD8^+$ to $CD4^+$ or $CD8^+$ cells. Humans deficient in ZAP-70 have $CD4^+$ but not $CD8^+$ T cells in the thymus and periphery.

$CD25^-CD44^-$ cells upregulate expression of CD4 and CD8 to become $CD4^+CD8^+$. It is as a $CD4^+CD8^+$ thymocyte that the α -chain of the TCR rearranges. Rearrangement of the α -chain can occur simultaneously on both chromosomes without allelic exclusion, and if one attempt is unsuccessful, repeat rearrangements to other V α segments are possible. Reports have been made of dual TCR expression by as many as 30% of mature T cells in which the same T cell expresses different α -chains paired with the same β -chain.

Although the structure of immunoglobulin and TCR is quite similar, they recognize fundamentally different antigens. Immunoglobulin recognizes intact antigens in isolation, either soluble or membrane-bound, and they are often sensitive to the tertiary structure. The TCR recognizes linear stretches of antigen peptide fragments bound within the grooves of either MHC class I or class II molecules (Fig. 9.2A) (Chapter 6). Thymic selection molds the repertoire of emerging TCR so that they recognize peptides within the groove of self-MHC molecules, ensuring the *self-MHC restriction* of T-cell responses. Pockets within the MHC groove bind particular residues along the peptide sequence of 7–9 amino acids for MHC class I, and 9–15 amino acids for MHC class II molecules. As a result, depending upon the particular MHC molecule, certain amino acids will make strong contact with the MHC groove while others will contact the TCR.

The contact between the TCR and antigen/MHC has been revealed by crystal structure to be remarkably flat, rather than a deep lock-and-key structure as one might imagine. The TCR axis is tipped about 30° to the long axis of the MHC class I molecule and is slightly more skewed to the MHC class II molecule.⁴ The affinity of the TCR for antigen/MHC is in the micromolar range. This is less than many antibody–antigen affinities, and several logs less than many enzyme–substrate affinities. This has led to the ideas that TCR interactions with antigen/MHC are brief and successful activation of the T cell requires multiple interactions resulting in a cumulative signal.

Once the T cell has successfully rearranged and expressed a TCR in association with the CD3 complex, it encounters the second major hurdle in T-cell development: thymic selection. Selection has two phases: positive and negative. The TCR must engage antigen–MHC complexes on thymic epithelium or dendritic cells which confer a certain low-affinity signaling that permits the developing thymocyte to survive and mature beyond the CD4⁺CD8⁺ stage (Fig. 9.1). This is known as *positive selection* and is coincident with upregulation of surface TCR, the activation markers CD5 and CD69, and the survival factor Bcl-2. T cells bearing a TCR that recognizes MHC class I maintain CD8 expression, downregulate CD4, and become CD4[−]8⁺. T cells expressing a TCR that recognizes MHC class II become CD4⁺8[−]. This cell fate is also influenced by the intensity of the TCR signal, with higher-affinity interactions favoring the CD4 lineage and with lesser TCR signal intensity favoring the CD8 pathway.⁵ Thymocytes bearing a TCR that does not engage any endogenous peptide–MHC complex are eliminated.

At the opposite extreme is *negative selection*, in which T cells expressing TCR complexes with too high an affinity for self-peptide–MHC complexes are eliminated by active cell death, known as apoptosis. The collective findings of several studies suggest a model in which the thymic processes of death by neglect, positive selection conferring survival, and negative selection represent a continuum of affinities from low to high of the various TCR for self-peptide–MHC complexes (Fig. 9.2B). Those at the extremes of low or high affinities are eliminated, while those with intermediate affinities survive to become mature T cells. The peptides that select the T-cell repertoire are not known. Studies in which endogenous peptides were eluted from MHC molecules found a variety of peptides, including sequences from housekeeping molecules. T cells from a transgenic mouse expressing a single MHC class II peptide complex manifest a broad repertoire and were fully functional.⁶ However, the mature T cells did not respond to the selecting MHC–peptide complex. This suggested

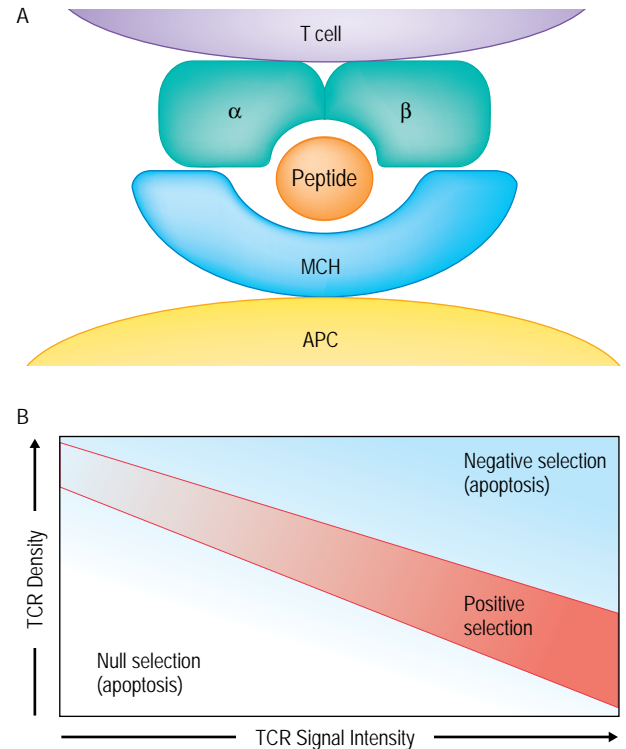

Fig. 9.2 Thymic selection. (A) Developing CD4⁺8⁺ T-cell receptor-positive (TCR⁺) thymocytes undergo positive selection by interaction with cortical epithelium. Those that fail to make such signals die through neglect. Surviving thymocytes then undergo negative selection primarily on medullary dendritic cells. Surviving thymocytes can then become mature CD4 or CD8 T cells. (B) TCR interaction with the major histocompatibility complex (MHC)–peptide complex. Polymorphic residues within the variable region of the α - and β -chains of the TCR make contact with determinants on the MHC molecule on an antigen-presenting cell (APC) as well as with the peptide fragment that sits in the MHC-binding groove. Schematic diagram illustrating that during thymocyte development, those TCR conferring either a very low signal intensity (null selection) or high intensity (negative selection) each lead to apoptosis. Only those thymocytes whose TCR can engage MHC/peptides and confer moderate intensity survive by positive selection.

that the threshold for triggering T cells during thymic development may be lower than that for the same T cell once it has matured.

A gene that is critical to the expression of self proteins by the thymic stromal cells is AIRE. AIRE is expressed at high levels by thymic epithelium, especially in the medulla. It is believed to promote the expression of several ectopic self proteins by the thymic epithelium, such as thyroglobulin and insulin.⁷ This promotes the negative selection of T cells reacting to these self proteins. Genetic absence of AIRE results in autoimmune disease of specific organs. This is known as the autoimmune polyendocrinopathy–candidiasis–ectodermal–dystrophy syndrome (APECED or APS1; Chapter 35). Patients manifest chronic mucocutaneous candidiasis

and autoimmunity most commonly of the parathyroid and adrenal glands, with lesser involvement of the skin, thyroid, and liver.⁸

Not surprisingly, a variety of signaling molecules are important to conferring positive selection. These include Lck, the Ras/Raf-1/MAP kinase cascade, the kinase ZAP-70, and the phosphatases CD45 and calcineurin, among others (Chapter 13). By contrast, although a number of molecules may promote negative selection, there appears to be sufficient redundancy so that only rarely does elimination of any one of these molecules affect deletion of thymocytes. The few exceptions include CD40, CD40L (CD154), CD30, or the Bcl-2 proapoptotic family member, Bim, where preservation of at least some thymocytes bearing self-reactive TCR could be observed in mice deficient in these molecules.

The survivors of these two stringent processes of TCR gene rearrangement and thymic selection represent fewer than 3% of total immature thymocytes. This is reflected by the presence of a high rate of cell death in developing thymocytes. This can be visualized by the measurement of DNA degradation using the TUNEL assay (Fig. 9.3) (Chapter 101). This technique labels nicked DNA using the ability of the DNA repair enzyme TdT to insert biotinylated dUTP residues at sites of double-stranded breaks. The survivors become either CD4 helper or CD8 cytolytic T cells and reside in the thymic medulla for 12–14 days before emigrating to the periphery.

EXTRATHYMIC T-CELL DEVELOPMENT

In the absence of a thymus, as in nude (*nu/nu*) mice, T-cell populations in the lymph nodes and spleen are severely reduced and oligoclonal, but they are not absent. Whereas some of this extrathymic T-cell development occurs within the liver, a significant amount also occurs in contact with the intestinal epithelium. It is less clear whether extrathymic development occurs in humans.

Intestinal intraepithelial lymphocytes (IEL) have a very different phenotype from thymus-derived T cells (Chapter 19). In contrast to the predominance of CD4 cells over CD8 T cells in normal lymph nodes, IEL contain large portions of CD8 and CD4⁺8⁺ T cells.⁹ Many of the CD8 IEL express only the CD8 α chain as an $\alpha\alpha$ homodimer. $\gamma\delta$ T cells also comprise a significant portion of IEL. The antigens to which IEL respond are not known, although in humans some of the $\gamma\delta$ IEL recognize the MHC class Ib molecule MICA via the stimulatory NK receptor, NKG2D.¹⁰ IEL have a memory CD44⁺ T-cell phenotype (see below) and are cytolytic when freshly isolated.

ABNORMALITIES OF EARLY HUMAN T-CELL DEVELOPMENT

Given the vast number of events in T-cell development, it is not surprising that a multiplicity of causes can underlie human T-cell immunodeficiencies (Chapter 35). The influence of the thymic stroma of thymocyte ontogeny is underscored, for instance, in the DiGeorge anomaly in which development of the pharyngeal pouches is disrupted and the thymic rudiment fails to form.¹¹ This results, predictably, in the failure of normal T-cell development. Less severe T-cell deficiencies are associated with a failure to express MHC class I and/or class II (the “bare lymphocyte syndrome”), which are directly involved with interactions required to

Fig. 9.3 TUNEL assay for nicked DNA in thymocytes undergoing apoptosis. Thymus sections were made from wild-type mice, fixed, and stained by the TUNEL assay. The DNA repair enzyme, TdT, inserts biotinylated dUTP residues at sites of double-stranded breaks, which is then revealed by avidin horseradish peroxidase. Shown are sections at 100 \times and 400 \times . Apoptotic thymocytes reflect those undergoing negative selection from either too intense or too weak a TCR signal.

induce the positive selection of, respectively, CD4 and CD8 single positive T cells.

Disorders can affect thymocytes more directly. The absence of functional adenosine deaminase and purine nucleoside phosphorylase results in the buildup of metabolic byproducts that are toxic to developing T and B lymphocytes, and ultimately produces forms of SCID. SCID can also result from the failure to generate lymphocyte precursors, for example due to abnormal or absent function of the RAG genes and other proteins associated with the gene rearrangement process.

The inability to express any number of surface molecules also has the potential to perturb development. The failure to express TCR-CD3 components (specifically CD3 γ), CD18, and IL-2R γ , and a defect in expression of CD3 ϵ have all been noted among patients who exhibit varying degrees of T-cell deficiency or dysfunction.

CLINICAL RELEVANCE

ABNORMALITIES OF T-CELL DEVELOPMENT

- >> The importance of the thymus is underscored by the complete absence of T cells in patients in whom a thymus has failed to develop (e.g., complete DiGeorge syndrome)
- >> T-cell development can be abrogated by the accumulation of toxic metabolites, such as seen in adenosine deaminase deficiency or purine nucleoside phosphorylase
- >> T-cell development requires expression of T-cell receptors (TCR), hence loss-of-function mutations in RAG and other associated genes typically results in the absence of T cells
- >> T-cell survival and development require signal transduction through the TCR signaling complex and associated co-receptors, hence loss-of-function mutations in TCR-CD3 components typically result in T-cell deficiency or dysfunction

PERIPHERAL MIGRATION OF T CELLS

The migration of naïve T cells to peripheral lymphoid structures or their infiltration into other tissues requires the coordinate regulation of an array of cell adhesion molecules. T-cell recirculation is essential for host surveillance and is carefully regulated by specific homing receptors. Entry from the circulation to tissues occurs via two main anatomic sites: the flat endothelium of the blood vessels and the specialized postcapillary venules known as high endothelial venules (HEV).

HEV are distinguishable by their cuboidal shape and are found primarily in lymph nodes. Endothelium resembling HEV can occur at certain sites of inflammation such as in rheumatoid synovium. It is not clear whether this represents differentiation of normal flat endothelium to HEV or a separate lineage of endothelial cells. HEV may offer a biological advantage over flat endothelium by presentation of the optimum architecture and concentration of homing receptor ligands.

A three-step model has been proposed for lymphocyte migration: rolling, adhesion, and migration¹² (Chapter 12). The selectins (CD62) can be expressed on leukocytes (L-selectin, CD62L, and vascular endothelium E-selectin, CD62E, and P-selectin, CD62P). L-selectin expressed by naïve T cells binds via lectin domains to carbohydrate moieties of GlyCAM-1 and CD34 (collectively known as peripheral node addressin), which are expressed on endothelial cells, particularly HEV. The weak binding of CD62L to its ligand mediates a weak adhesion to the vessel wall which, combined with the force of blood flow, results in rolling of the T cell along the endothelium. The increased cell contact facilitates the interaction of a second adhesion molecule on lymphocytes, the integrin LFA-1 (CD11a/CD18) with its ligands, ICAM-1 (CD54) and ICAM-2 (CD102). This results in the arrest of rolling and firm attachment.

Migration into the extracellular matrix of tissues may involve additional lymphocyte cell surface molecules such as the hyaluronate receptor (CD44) or the integrin $\alpha 4 \beta 7$ (CD49d/ $\beta 7$) that binds the mucosal addressin cell adhesion molecule-1 (MAdCAM-1) on endothelium of Peyer's patches and other endothelial cells. Additional molecules may be involved with tissue infiltration. These include cutaneous lymphocyte-associated (CLA) antigen that is expressed by the majority

of memory T cells and binds to E-selectin on endothelium of inflamed skin, as well as other pairs such as CD49d/CD29 ($\alpha 4 \beta 1$ /VLA-4). Expression of these receptors is regulated by inflammatory cytokines (Chapters 10 and 17). Other cytokines known as chemokines may contribute to lymphocyte homing (Chapter 11). Chemokines are structurally and functionally related to proteins bearing an affinity for heparan sulfate proteoglycan and promote migration of various cell types. The chemokines RANTES, MIP-1 α , MIP-1 β , MCP-1, and IL-8 are produced by a number of cell types, including endothelium, activated T cells, and monocytes, and are present at inflammatory sites such as rheumatoid synovium. A number of chemokine receptors are important for migration of developing thymocytes through the thymic stroma. These include CCR4 (ligand = CCL17 and CCL22), CCR7 (ligand = CCL19), CCR9 (ligand = CCL25), and CXCR4 (ligand = CXCL12 or SDSF1).

SUBSETS, FUNCTION, AND THE DEVELOPMENT OF PERIPHERAL T CELLS

CD4 HELPER AND CD8 CYTOLYTIC T CELLS

$\alpha \beta$ T cells can be subdivided into two main subsets based on their recognition of peptides presented by MHC class I or class II molecules and their respective expression of CD8 or CD4. The peptides presented by MHC class I molecules are produced by the proteasome and can be derived from either self proteins or intracellular foreign proteins as might occur during viral replication. MHC class II-bound peptides are largely derived from extracellular infectious agents or self cell surface proteins that have been engulfed and degraded in the lysosomal complex.

CD4 T cells express a variety of cytokines and cell surface molecules that are important to B-cell proliferation and immunoglobulin production. Following antigen stimulation, CD4 T cells differentiate into two major classes of effector T cells called T helper 1 (Th1) and Th2 (Chapter 17). In brief, Th1 cells participate in cell-mediated inflammatory reactions, activate macrophages, and produce IL-2, LTX α , and interferon- γ . Th2 cells activate B cells and produce IL-4, IL-5, IL-6, IL-10, and IL-13. IL-4 and IL-5 are important B-cell growth factors, as are surface CD40 ligand and the recently described BAFF. In addition, IL-4 promotes B-cell secretion of IgG₁ and IgE, whereas interferon- γ drives IgG_{2a} production. Since Th1 and Th2 cells mediate different functions, the type of response generated can influence susceptibility to disease.

The CD4 molecule is structurally related to immunoglobulins and has an affinity for nonpolymorphic residues on the MHC class II molecule. In this capacity CD4 presumably increases the efficiency with which CD4 T cells recognize antigen in the context of class II molecules, which are restricted in their expression to B cells, macrophages, dendritic cells, and a few other tissues during states of inflammation. In addition, the cytoplasmic tail of CD4 binds to Lck and promotes signaling by the TCR, as described earlier. However, ligation of CD4 prior to engagement of the TCR renders the T cell susceptible to apoptosis upon subsequent engagement of the TCR. This is clinically important in human immunodeficiency virus (HIV) infections in which the gp120 molecule of HIV binds to CD4 and primes the T cell to undergo cell death when

later triggered by the TCR. Accelerated apoptosis of CD4 T cells has been demonstrated in acquired immunodeficiency syndrome (AIDS) patients.¹³

CD8 T cells are very efficient killers of pathogen-infected cells. Given the ubiquitous expression of class I molecules, mature cytolytic T cells (CTL) can recognize viral infections in a wide array of cells, in distinction to the more restricted distribution of class II molecules and their recognition by CD4 T cells. CTL induce lysis of target cells through the production of perforin, which induces holes in cell membranes, and the expression of FasL and tumor necrosis factor- α (TNF- α), which induce apoptosis. In this capacity CTL kill virally infected target cells in an attempt to restrict the spread of infection. Similar to CD4, CD8 manifests an affinity for MHC class I molecules, enhances the signaling of TCR, and also binds Lck by its cytoplasmic tail.

■ T CELLS IN THE INNATE IMMUNE RESPONSE ■

In addition to the broad array of antigens recognized by $\alpha\beta$ T cells, there is growing appreciation that the immune system also contains small subpopulations of T cells, $\gamma\delta$ and natural killer (NK) T cells, that function as important constituents of the innate immune system. These cells may be specialized to recognize conserved structures that are either uniquely expressed by prokaryotic pathogens or on stressed host cells (Chapter 3). The receptors used to recognize these nonpolymorphic molecules may themselves be less polymorphic, such as the Toll-like receptor (TLR) family and MHC class I-like CD1 family. For example, TLR4 expressed on macrophages and dendritic cells binds lipopolysaccharide (LPS) and products of Gram-negative bacteria, whereas TLR2 binds lipopeptides from organisms such as the LPS-deficient Lyme disease spirochete, *Borrelia burgdorferi*. By focusing on such common and far less polymorphic molecules, the immune response may be able to respond quickly during the early phase of infections.

$\gamma\delta$ T CELLS

The $\gamma\delta$ T cell is among the oddest of immunology's distinguished oddities. Their study stems from the discovery of rearranged genes rather than a knowledge of their biological function. Transcription of rearranged γ and δ genes begins prior to $\alpha\beta$ genes. Rearranged γ and δ genes are first expressed in the liver and primitive gut between 6 and 9 weeks' gestation. In addition to the ordered appearance of $\gamma\delta$ TCR before $\alpha\beta$ TCR, there is also a highly ordered expression of γ and δ V-region genes during early development. The reason for this remarkable regimentation remains unclear.

$\gamma\delta$ T cells manifest a number of differences from $\alpha\beta$ T cells. $\gamma\delta$ T cells are often anatomically sequestered to epithelial barriers or sites of inflammation,¹⁴ and frequently manifest cytotoxicity toward a broad array of targets. In contrast to $\alpha\beta$ T cells, $\gamma\delta$ cells can respond to antigen directly, without evidence of MHC restriction, or conversely, react to MHC molecules without peptide.

Human $\gamma\delta$ T-cell clones, particularly those expressing the V δ 2 gene and derived from peripheral blood of normal individuals or synovial fluid of rheumatoid arthritis patients, frequently react to mycobacterial extracts.¹⁵ While a few of these V δ 2 clones respond to a heat shock protein, the major stimulatory components have recently been identified

as phosphate-containing nonpeptide molecules such as nucleotide triphosphates, prenyl pyrophosphates, and alkylamines.¹⁶ These molecules are, respectively, subunits in DNA and RNA, substrates in lipid metabolism for the synthesis of farnesyl pyrophosphate, and products of pathogenic organisms. In mammalian cells, farnesyl addition is a critical modification for targeting certain signaling molecules, such as Ras to the cell membrane. This process appears critical to cell transformation. These phosphate-containing nonpeptides can be found in both microbial and mammalian cells. This suggests that $\gamma\delta$ cells may recognize a class of antigens shared by a number of pathogens, as well as by damaged or transformed cells, and may provide insight into the role of $\gamma\delta$ cells in infection and their accumulation at sites of inflammation. A subpopulation of $\gamma\delta$ T cells typically found in the intestine and expressing the V δ 1 gene (which is also found in inflamed synovial fluid) was shown to react to MHC class I-like molecules known as MICA and MICB.¹⁰ Unlike classical MHC class I molecules that are expressed ubiquitously and continuously, MICA and MICB expression appears to be restricted to epithelium and occurs only during times of stress, similar to that of a heat shock response. The NK receptor NKG2D on human V δ 1 T cells was determined to be a receptor for the MHC class Ib molecule MICA.¹⁰ It remains to be determined whether V δ 1 TCR itself recognizes MICA or another as-yet undetermined structure. Some V δ 1 T cells have been suggested to respond to CD1c.

The contribution of $\gamma\delta$ T cells to defense against infection has been examined in mice using a number of pathogens, including *Listeria*, *Leishmania*, *Mycobacterium*, *Plasmodium*, and *Salmonella*. All of these studies have shown a moderately protective role for $\gamma\delta$ T cells. In some cases of rapid bacterial growth, $\gamma\delta$ T cells appear to be protective early during infection by reducing bacterial growth, whereas in less virulent infections such as influenza or Sendai virus, $\gamma\delta$ cells appear later in inflammatory lesions. In only a few instances, however, have $\gamma\delta$ clones derived from an infected animal been shown to respond to the causative organism. In human infections, $\gamma\delta$ T cells from cutaneous lesions of leprosy patients respond to *Mycobacterium leprae*,¹⁷ and $\gamma\delta$ cells from Lyme arthritis synovial fluid will respond to the causative spirochete, *Borrelia burgdorferi*.¹⁸ This response by Lyme synovial $\gamma\delta$ cells requires lipidated hexapeptides of the outer-surface proteins of *B. burgdorferi*, and the tripalmitate lipid moiety is as important for activation of $\gamma\delta$ T cells as the hexapeptide portion. The same motif binds TLR2 and may thus indirectly activate $\gamma\delta$ T cells.

$\gamma\delta$ T cells accumulate at inflammatory sites in autoimmune disorders such as rheumatoid arthritis, celiac disease, and sarcoidosis.¹⁹ The reason for this remains an enigma. However, there is evidence that $\gamma\delta$ can be highly cytolytic toward a variety of tissues, including CD4 T cells, and their presence can strongly bias the cytokine profiles of the infiltrating CD4⁺ cells, in some instances toward Th1 profiles, and in others toward Th2.²⁰

NK T CELLS

A minor subpopulation of T cells bearing the NK determinant manifest perhaps the most restricted of TCR repertoires and determinants of recognition. NK T cells are found within the CD4 and CD4⁺8⁻ subsets of T cells and, in both mouse and human, express a very limited number of TCR-V β chains and an invariant α -chain.²¹ Furthermore, NK T cells are restricted in their response to a monomorphic MHC class I-like molecule, CD1d. Crystallographic analysis of CD1 has shown that it

KEY CONCEPTS

NAÏVE VERSUS MEMORY T CELLS

CD4 and CD8 T cells emigrate from the thymus bearing a naïve phenotype

Naïve T cells:

- >> Produce IL-2, but only low levels of other cytokines
- >> Require continual major histocompatibility complex (MHC)/self-peptide interactions in the periphery for survival
- >> Express the CD45RA isoform of CD45

Memory T cells:

- >> Express a variety of surface molecules involved with cell adhesion and migration, activation, cytokine production, T-cell proliferation, and death receptors
- >> Survive for long periods in the absence of MHC/peptide signaling
- >> Are activated more rapidly than naïve T cells
- >> Express the CD45RO isoform of CD45

contains a deeper groove than traditional MHC molecules and is highly hydrophobic, suggesting it may bind lipid moieties.²¹ This may represent another type of innate T-cell response whereby bacterial lipids or lipopeptides may be presented to NK T cells to provoke a rapid early immune response.

The potential importance of NK T cells in autoimmune disease stems from their production of high levels of certain cytokines, particularly IL-4.²¹ In this capacity, they may be important for inhibiting inflammatory responses dominated by Th1 infiltrates. This has been noted in the non-obese diabetic (NOD) mouse model of diabetes that lacks NK T cells. Adoptive transfer of NK T cells into NOD mice blocks the onset of diabetes.²² A recent study extended this observation to human type 1 diabetes. The NK T cells of diabetic individuals produced more interferon- γ and less IL-4 than their unaffected siblings.²³ Thus, this minor population of T cells may play a pivotal role in early innate responses to certain infections and also in the regulation of inflammatory lesions.

NAÏVE VERSUS MEMORY T CELLS

CD4 and CD8 T cells emigrate from the thymus bearing a naïve phenotype. Naïve T cells produce IL-2 but only low levels of other cytokines, and as such manifest little B-cell helper activity. They express high levels of Bcl-2 and can survive for extended periods without antigen but require the presence of MHC molecules. Naïve T cells circulate from the blood to lymphoid tissues of the spleen and lymph nodes that concentrate antigen, antigen-presenting cells (APC), T cells and B cells. Particularly important in this environment as APC are dendritic cells, which are derived from both lymphoid and myeloid progenitors and are particularly adept at concentrating and presenting antigen. Dendritic cells can migrate from other areas of the body such as the skin and thus transport antigen to lymphoid tissues. These specialized cells optimize concentrations of antigen/MHC molecules, co-stimulatory molecules,

and cytokines to promote clonal expansion of antigen-specific T cells, which may be present at as low a frequency as 1 in 10^6 prior to immunization, but can increase to 1 in 1000 or more within 1 week. The development of antigen peptide/MHC tetramer technology has led to a more direct quantitation of these values using flow cytometry and suggests their frequency may be considerably higher.

During the process of clonal expansion of naïve T cells and their differentiation into effector and eventually memory T cells, as many as 100 genes are induced. These are manifest primarily as increased expression of certain surface molecules involved with cell adhesion and migration (e.g., CD44, ICAM-1, LFA-1, $\alpha 4\beta 1$, and $\alpha 4\beta 7$ integrins), activation (e.g., CD45 change from high-molecular-weight CD45RA to lower-molecular-weight CD45RO isotype), cytokine production (increased production of interferon- γ , IL-3, IL-4, and IL-5) and death receptors (e.g., Fas/CD95). More transiently induced are CD69, the survival factor BCL-xL, and the high-affinity IL-2 receptor α -chain (CD25), the last being necessary for T-cell proliferation.

Although the concept of immune memory has existed since the first successful vaccinations by Jenner for smallpox, the first T-cell memory marker, CD44, was not identified until 1987. Prior to the identification of this marker, memory T cells could only be identified at a functional level by demonstrating the presence of an enhanced proliferative response of peripheral blood lymphocytes from an individual previously vaccinated against an antigen such as tetanus toxoid. CD44 was absent on mature single positive T cells as they emerged from the thymus, but its expression was induced upon the first encounter with antigen stimulation in the periphery. Since then several other markers have been shown to change upon primary antigenic stimulation. Most notable for human T cells is CD45, in which an isoform known as CD45RA is expressed on naïve T cells, whereas CD45RO expression characterizes memory T cells. Using these markers it has been possible to identify a variety of differences between naïve and memory T cells. Activation of memory T cells appears to be more efficient than that of naïve T cells. The signals required for maintenance of naïve versus memory T cells also differ. Naïve T cells require continual MHC/self-peptide interactions in the periphery, while both CD4 and CD8 memory T cells can survive for long periods in the absence of MHC/peptide signaling.²⁴

TH1 VERSUS TH2 T CELLS

In response to repetitive antigenic stimulation, responding CD4 cells can differentiate into effector cells expressing polarized patterns of cytokine production. Th1 cells are characterized by production of IL-2, interferon- γ , TNF α , and LTX α , whereas Th2 cells produce IL-4, IL-5, IL-6, IL-10, and IL-13²⁵ (Chapters 10 and 17). These patterns have been best characterized during chronic infections. In general, a Th1 response helps eradicate intracellular microorganisms, such as *Leishmania major* and *Brucella abortus*, whereas a Th2 cell response can better control extracellular pathogens, such as the helminth, *Nippostrongylus brasiliensis*. The cytokine profiles of Th1 and Th2 cells are mutually inhibitory, such that the Th1 cytokines interferon- γ and IL-12 suppress Th2 responses, whereas the Th2 cytokine IL-4 suppresses Th1 responses.

Polarization of the cytokine environment also occurs at the sites of inflammation in many autoimmune syndromes. Th2 skewing has been observed in models of systemic lupus erythematosus, where increased levels of immunoglobulins and autoantibodies are typical, as well as in chronic allergic conditions such as asthma. Frequently, however,

the infiltrating lymphocytes exhibit a bias toward Th1 cytokines. This occurs with brain-infiltrating lymphocytes in multiple sclerosis and its animal model experimental allergic encephalomyelitis (EAE), β -islet lymphocytes in diabetes, and synovial lymphocytes in inflammatory arthritides.²⁶ Unlike the beneficial effects of Th1 responses during infections, these same cytokines can be quite deleterious in autoimmune disorders. Thus, therapies based on inhibition of certain Th1 cytokines have been of considerable interest and often are ameliorative, such as anti-TNF- α treatment of EAE and in human trials of rheumatoid arthritis.²⁷

Co-stimulatory molecules and other cytokines produced by APC can also influence cytokine polarization. CD80 (B7-1) and IL-12 promote a Th1 emergence whereas CD86 (B7-2), IL-4, IL-6 can evoke a Th2 predominance. Th1 cells are also generally thought to be more easily tolerized and more susceptible to activation-induced cell death (AICD), perhaps because they express more FasL than Th2 cells. Increased expression of Fas-associating phosphatase-1 (FAP-1) by Th2 cells may also contribute to their resistance to AICD by inhibiting Fas signaling. However, other investigators have observed that Th1 and Th2 cells are equally sensitive to apoptosis upon Fas ligation.

REGULATORY T CELLS

In addition to the tolerance that results from the deletion of autoreactive T cells, a subpopulation of T cells known as regulatory T cells or Treg has been identified that suppresses the proliferation of other T cells²⁸ (Chapter 16). Treg have the phenotype CD4⁺CD25⁺ and arise during thymic development. Their appearance is delayed in neonatal thymectomy, and this procedure is known to lead to an autoimmune syndrome of various target organs.²⁸ Treg express the forkhead transcription factor Foxp3, which plays a critical role in their function, and Foxp3 expression determines the cell fate independently of any other surface marker.²⁸ Various autoimmune disorders have been associated with reduced levels of Treg²⁹ (Chapter 50).

DEATH OF T CELLS

The rapid removal of the effector T cells following clearance of the infection is as important as the clonal expansion of responding T cells for the health of the organism. Failure to clear activated lymphocytes increases the risk of cross-reactivity with self antigens and a sustained autoimmune reaction. To insure that resolution of an immune response occurs rapidly, a number of processes promote active cell death as T cells clonally expand. One means to control T-cell proliferation is through limited availability of growth factors. Upon activation, T cells express receptors for various growth cytokines for approximately 7 days, but only produce cytokines during the first 48 hours. This results in an unstable situation where T cells tend to outgrow the availability of cytokines. T cells expressing IL-2R, for example, in the absence of IL-2 will rapidly undergo programmed cell death.

The discovery of a family of death receptors expressed by T cells elucidated an additional regulatory process. These molecules are described more extensively in Chapter 14 and will only be discussed here as they relate to T-cell function. The best described of these is Fas (CD95). Ligation of Fas recruits the adaptor molecule, FADD, which in turn recruits caspase-8, the first in a series of proteases that promote cell death. Nearly all cells have some level of surface Fas, whereas expression of its ligand (FasL) is primarily restricted to activated T cells and B cells.

Consequently, regulation of Fas-mediated apoptosis is to a large extent under the governance of the immune system. FasL expression has also been reported for certain components of the eye, the Sertoli cells of the testis, and perhaps some tumors.³⁰

Expression of FasL by these nonlymphoid cells is thought to prevent immune responses at sites where such inflammation might cause tissue damage. For years immunologists have been aware of these so-called “immune-privileged” sites within which immune responses are difficult to initiate.

During T-cell activation, expression of FasL is rapidly induced at the level of RNA and the ability to kill Fas-sensitive target cells is easily demonstrated. Yet expression of surface FasL protein has been difficult to demonstrate. This may be due to a sensitivity of surface FasL to certain proteinases, which results in its rapid cleavage and release from the cell in a manner similar to the release of another member of the Fas family TNF- α . Resting T cells are not sensitive to Fas-induced death, but must first enter the cell cycle for approximately 3 days. During this period, the cellular level of an endogenous inhibitor of Fas known as FLIP is down-regulated, and this presumably allows Fas signaling to progress. Thus, FLIP may function to protect resting T cells from unnecessary death and restrict apoptosis to activated T cells in order to limit their expansion. The importance of FLIP as an inhibitor of cell death is reinforced by the discovery that certain herpes viruses express a homologue of mammalian FLIP called E8 that can prevent death of host cells.³¹ E8 expression may alter the tumorigenic potential of herpes viruses.

Mutations of Fas have been identified in humans and these patients present with an autoimmune syndrome, often hemolytic anemia associated with hypergammaglobulinemia (both of IgG and IgA) and lymphadenopathy consisting of an unusual population of TCR- $\alpha\beta$ ⁺ CD4⁺CD8⁻ (“double-negative”) T cells. Somewhat unexpected was the finding that mutations in caspase-8 did not produce the same syndrome. Instead they result in a syndrome of immunodeficiency in which the T cells do not proliferate efficiently upon activation, have defective activation of NF- κ B after TCR ligation, and produce greatly decreased levels of IL-2. A similar observation was made in mice lacking caspase-8 in T cells. These findings underscore the importance of a newly defined function of caspase-8 in T-cell activation of resting T cells, in addition to its role in cell death of actively cycling effector T cells.

The sequence of T-cell activation followed by cell death is graphically displayed following the administration to mice of bacterially or virally derived compounds called superantigens (Chapter 6). Superantigens activate T cells by directly cross-linking MHC class II molecules with particular β -chain V families of the TCR. The superantigen staphylococcal enterotoxin B (SEB) strongly activates V β 8⁺ T cells.³² This initiates a rapid expansion of V β 8⁺ T cells over 2–3 days, followed by an equally rapid loss of these cells. By day 7 very few V β 8⁺ T cells remain. This elimination phase is largely dependent on the pro-apoptotic Bcl-2 member, Bim.³³ A similar process occurs during homeostatic proliferation in which naïve T cells undergo spontaneous cell cycling in a lymphopenic environment³⁴ but are also deleted so that autoimmunity does not arise. The proliferation is regulated by IL-7 and self-MHC/peptides, whereas the deletion phase is regulated by Fas.³⁵ This likely explains the adenopathy that occurs in Fas-deficient *lpr* mice.

A similar process of superantigen-induced T-cell activation occurs in the human disease toxic shock syndrome in which a related staphylococcal superantigen/toxin, TSST, stimulates the expansion of V β 2⁺ T cells.³⁶ The devastating illness that results from this profound activation of a

large proportion of T cells underscores the need to eliminate activated T cells rapidly. At least some of the damage in toxic shock syndrome likely results from the extensive T-cell expression of FasL and TNF α , particularly in certain tissues such as the liver. Hepatocytes are exquisitely sensitive to damage by these ligands. Activation of T lymphocytes leads to homing to the liver and administration of antigen to TCR transgenic mice can yield a syndrome resembling autoimmune hepatitis. Thus, certain autoimmune disorders may result from the death or damage of 'innocent bystander' cells as a consequence of the migration of activated T cells to an organ and nonspecific damage due to the expression of FasL family members.

The life of a T cell from its infancy as a differentiating thymocyte to its death as a mature peripheral effector cell is regulated by a series of tightly coordinated genetic events linked to phases of rapid expansion of cell number followed by equally rapid programmed cell death. The expansion is paramount for combating infections while death is required to obviate the emergence of self-reactive T cells. Aberrations of either process can lead to immunodeficiency or autoimmune sequelae. The clinical consequences of each are discussed in subsequent chapters.

Cytokines and cytokine receptors

John O'Shea, Cristina M. Tato, Richard Siegel

10

Cytokines play pivotal roles in the function of a variety of cells, but are of particular interest to immunologists because of their importance in immune regulation. They are also clinically relevant in terms of both disease pathogenesis and, increasingly, treatment. However, one of the barriers to learning about cytokines is a complicated nomenclature and system of classification. In part, this reflects the nonspecificity of the term cytokine. It does not encompass a class of factors that are structurally or functionally related: rather, it includes a number of different factors produced by lymphoid and nonlymphoid cells that mediate intercellular communication. The confusion in terminology arises partly from the history of the field. The various cytokines were discovered by researchers in several disciplines, including immunology, virology and hematology, and many marked their cytokine with their original set of interests.

The term lymphokine was originally used to denote products of lymphocytes,¹ but Cohen et al.² coined the word cytokine to emphasize the point that these factors need not be made by one specific cell source. This was an important insight, because many immunologically relevant cytokines are made by nonlymphoid cells. Later, the term interleukin was introduced to emphasize the importance of these factors in communication between leukocytes.³ Although this designation has remained in use, it is similarly inaccurate. Many of the polypeptides designated interleukins can also be made by or act on nonhematopoietic cells. Cytokines can be defined operationally as polypeptides secreted by leukocytes and other cells that act principally on hematopoietic cells, and whose effects

include modulation of immune and inflammatory responses. However, there are clear exceptions to even this broad definition. Some definitions distinguish cytokines from hormones and growth factors, which act on nonhematopoietic cells. Thus, cytokines are typically characterized as factors made by more than one cell type and act locally, whereas hormones are secreted by specialized cells and act at a distance on a restricted set of target cells. Although many cytokines act locally in an autocrine or paracrine fashion, some do enter the bloodstream and can act in a typical endocrine fashion. Consequently, the boundary between cytokines and hormones is rather indistinct. In fact, classic hormones such as growth hormone (GH), prolactin (PRL) and erythropoietin (EPO) are clearly cytokines, as is one of the newest hormones, leptin, as evidenced by the type of receptor they bind and their modes of signaling. As we learn more, there are clear functional similarities and evolutionary relationships among these families of molecules that act on the immune, hematopoietic, endocrine and nervous systems.

A major challenge in discussing cytokines is their classification. One way is to group the factors by function, e.g., factors that regulate hematopoietic, inflammatory or immune cells. However, an important characteristic of cytokines is that they are often pleiotropic in their effects. Cytokines can have multiple target cells and consequently multiple actions. Secondly, structurally dissimilar cytokines can have overlapping but typically nonidentical actions, a given effect often being mediated by several different cytokines. This is termed cytokine redundancy. Finally, a single cytokine frequently induces or influences the action of other cytokines, and can function synergistically. Thus understanding the exact properties of a given cytokine is a challenge. However, this complexity of cytokine action has been simplified to an extent by the generation of cytokine gene targeted mice.

The complexity in terms of action provides a strong rationale for an alternative nomenclature, and that is to group cytokines according to the type of receptor that they bind rather than by their function. This classification is also useful because it reflects the evolutionary relatedness of cytokines, growth factors and hormones, and emphasizes similarities in modes of signal transduction. The classification used in this chapter is adapted from Vilcek⁴ and includes the following receptors: the so-called type I (hematopoietin family) and type II (interferon family) cytokine

KEY CONCEPT

CYTOKINE CHARACTERISTICS

- >> Cytokines have pleiotropic effects: they may have more than one receptor.
- >> Cytokines can be redundant – their receptors often share subunits.
- >> Cytokines can have specific and unique functions – their receptors typically have ligand-specific subunits as well.

receptors, tumor necrosis factor (TNF) family receptors, interleukin (IL)-1 receptor and the related Toll-like receptors (TLRs), IL-17 receptors, receptor tyrosine kinases, and the TGF- β family receptor serine kinases (Table 10.1, Fig. 10.1). This chapter reviews in detail only a selected set of cytokines with important immunological functions.

■ TYPE I AND II CYTOKINE RECEPTORS (HEMATOPOIETIN FAMILY AND INTERFERON RECEPTORS) ■

LIGAND AND RECEPTOR STRUCTURE

Cytokines (Table 10.1) that bind the class of receptors termed the type I or hematopoietic cytokine receptor superfamily include hormones such as EPO, thrombopoietin (TPO), PRL, GH, and leptin; colony-stimulating factors (CSF) such as granulocyte (G)-CSF, granulocyte-macrophage (GM)-CSF; and interleukins (IL)-2-IL-7, IL-9, IL-11-IL-13, IL-15, IL-21, IL-23, IL-27, IL-31, and IL-35. Also included in this family are ciliary neurotrophic factor (CNTF), leukemia inhibitory factor (LIF), oncostatin M (OSM), and cardiotropin 1 (CT-1). Closely related are the interferons (IFN- α , - β , - τ , - ω , limitin) and IL-10-related cytokines, IL-19, IL-20, IL-22, IL-24, IL-26, and interferon-related cytokines IL-28A (IFN- γ 2) IL-28B (IFN- γ 3), IL-29 (IFN- γ 1), which bind type II receptors. The ligands and receptors in this superfamily are structurally similar and utilize related molecules for signal transduction.⁵

A central feature of type I cytokines is a similarity in their basic structure. Each contains four anti-parallel α helices with two long and one short loop connections arranged in an up-up-down-down configuration. Because of this structure, these cytokines have also been referred to as the α -helical bundle cytokine family.

Structurally, the receptors in the type I family have conserved cysteine residues, a conserved Trp-Ser-X-Trp-Ser motif (where X indicates any amino acid), and fibronectin-like repeats in their extracellular domains. These receptors have a single transmembrane domain and divergent cytoplasmic domains. Within the cytoplasmic portion of these receptors two segments of homology can be discerned, termed the Box 1 and Box 2 motifs. The membrane proximal domain binds Janus kinases (Jaks; see below). Some of the cytokine receptors are homodimers, such as the receptors for EPO, TPO, PRL and possibly leptin; whereas other receptors for type I cytokines are heterodimers, containing two distinct receptor subunits. Based on this characteristic, the type I family of receptors can be divided into subfamilies. Each member of the subfamily uses a shared receptor subunit in conjunction with a ligand-specific subunit. For example, the receptors for IL-2, IL-4, IL-7, IL-9, IL-15 and IL-21 all use a common cytokine γ chain, γ_c (Table 10.1), whereas a common β chain, β_c , is shared by IL-3, IL-5 and GM-CSF. Similarly, gp130 is a shared subunit for IL-6 family cytokines (IL-6, IL-11, IL-27, IL-31, CNTF, LIF, OSM and CT-1). IL-12 and IL-23 also share a receptor subunit, as do members of the IL-10 family.

Other levels of shared receptor usage also exist. For example, the receptors for LIF, CNTF, OSM, and CT-1 all share the LIF receptor subunit, whereas IL-2 and IL-15 utilize the same β and γ_c chains. Conversely, IL-4 can bind two different receptor complexes. The classic IL-4 receptor is composed of the IL-4R α chain and the γ_c chain. Additionally,

IL-4 can also bind the IL-13 receptor, which comprises a heterodimer of the IL-4R α chain and the IL-13R α chain. IL-13 only utilizes the IL-13 receptor complex for signaling.

The utilization of common receptor subunits explains the phenomenon of shared biological activities (cytokine redundancy) between cytokines that belong to the same subfamily. Within a subfamily, actions distinct for each cytokine can be attributed, at least in part, to the ligand-specific subunits. The pleiotropic effects of a single cytokine can be accounted for by the existence of more than one receptor for that cytokine.

Family members and their actions

Homodimeric receptors

Many of the cytokines that use homodimeric receptors are classic hormones; these include the factors GH, PRL and leptin. Several hormones that regulate hematopoiesis also exist as homodimers. EPO, for example, is required for erythrocyte growth and development and is widely used to treat anemia. Similarly, TPO is required for megakaryocyte development and may have a use in the treatment of thrombocytopenia. G-CSF regulates the production of neutrophils through its action on committed progenitor cells, but also supports the survival of mature neutrophils, enhancing their functional capacity. G-CSF is widely used clinically to treat patients with granulocytopenia. As one would predict, G-CSF knockout mice have marked neutropenia. In addition, mutations of the G-CSFR result in severe congenital neutropenia in humans.

Cytokine receptors utilizing gp130

gp130 is a receptor component for IL-6, IL-11, IL-27, and IL-31, as well as for several cytokines that are important in development.⁶ Targeted disruptions of the gp130 gene are lethal in early embryogenesis. The mice exhibit defects in myocardial, hematological, and placental development. LIF binds to a receptor that comprises gp130 in association with the LIF receptor (LIFR), as do the cytokines OSM, CNTF, and CT-1. Targeted disruptions of the LIFR gene are also embryonically lethal, creating defects in placental architecture and developmental abnormalities in neural tissue and bone. Targeted disruptions of LIF lead to failure of blastocyst implantation. Another critical role of LIF is the maintenance of stem cell pluripotency in culture.

Interleukin-6

The IL-6 receptor (IL-6R) consists of an 80 kDa IL-6 binding protein (α chain) and gp130. IL-6 has a wide array of biological actions on both lymphoid and nonlymphoid cells. It is important in host defense and in inflammatory responses; accordingly, IL-6-deficient mice are highly susceptible to infection by *Candida* and *Listeria*. IL-6 is an important growth and differentiation factor for B cells, inducing the production of immunoglobulin, including IgE. IL-6^{-/-} mice have normal numbers of B cells, but have a reduced immunoglobulin response to neoantigen and a marked reduction in IgA production. IL-6 also promotes T-cell growth and differentiation. Consequently, IL-6^{-/-} mice have reduced numbers of thymocytes and peripheral T cells. IL-6 is also important for Th17 differentiation. In addition, the cytotoxic T-cell response to viruses is impaired. IL-6 functions synergistically with IL-3 in hematopoiesis, and IL-6-deficient mice have reduced numbers of progenitor cells.

Table 10.1 Cytokines classified by receptor families

Receptor family	Subfamily	Cytokine	Signaling	Source	Target	Action	Knockout phenotype
Type 1 (hematopoietin)	Homodimeric	GH	JAK2, STAT5b	Two GH genes, pituitary, placental	Diverse tissues	Growth, adipocyte differentiation	Dwarfism
		Prl	JAK2, STATa	Two Prl genes pituitary, uterus	Mammary epithelium	Growth, differentiation	Infertility, lactation defects
		Epo	JAK2, STAT5	Kidney, Liver	Erythroid precursors	Erythroid differentiation	Embryonic lethal, severe anemia
		Tpo	JAK2, STAT5	Liver, Kidney	Committed stem cells and megakaryocytes	Platelet	Severe thrombocytopenia
		Leptin	JAK2/STAT3	Adipocytes	Hypothalamus, thyroid	Satiety, controls metabolic rate	Obesity
		G-CSF	JAK2, STAT3	Many tissues, macrophages, endothelium, fibroblasts	Committed progenitors	Differentiation, activates mature granulocytes	Neutropenia
	gp130-utilizing	IL-6	JAK1, STAT3	Macrophage, fibroblasts, endothelium, epithelium, T cells, other	Liver, B cell, T cell, thymocytes, myeloid cells, osteoclasts	Acute-phase reactants proliferation, differentiation co-stimulation	Reduced Ig, esp. IgA, T lymphopenia, impaired acute-phase response, and Th17 cells
		IL-11	JAK1, STAT3	Stromal cells	Hematopoietic stem cells	Proliferation	Female infertility
		IL-27	JAK1, STAT1, STAT3, STAT4, STAT5	DC	T and NK cells, other cells	Enhancement of Th1 responses, and IL-10; inhibition of Th1, Th2, and Th17 responses	Fatal inflammatory disease with infection
		IL-31	JAK1, STAT3, STAT5	Th2 cells	Monocytes, epithelial cells	Induces chemokines, PMN recruitment	
		CNTF ⁺	JAK1, STAT3	Schwann cells	Neuronal	Survival	Progressive atrophy and loss of motor neurons
		LIF ⁺	JAK1, STAT3	Uterus, macrophage, fibroblasts, endothelium, epithelium, T cells	Embryonic stem cells, neurons hematopoietic	Survival	Decreased hematopoietic progenitors, defective blastocyst implantation
		Osm ^a	JAK1, STAT3	Macrophage, fibroblasts, endothelium, epithelium	Myeloid cells, liver, embryonic stem cells	Differentiation, acute-phase induction	

Continued

Table 10.1 Cytokines classified by receptor families—Cont'd

Receptor family	Subfamily	Cytokine	Signaling	Source	Target	Action	Knockout phenotype
B _c -utilizing		CT-1	JAK1, STAT3	T cells, others, Myocardial	Myocardium	Growth	
		GM-CSF	JAK1, STAT3	T cells, macrophages, endothelium, fibroblasts	Immature and committed myelomonocytic progenitors macrophages and granulocytes, DC	Growth, differentiation survival, activation	Pulmonary alveolar proteinosis
		IL-3	JAK2, STAT5	T cell	Immature hematopoietic progenitors of multiple lineages	Growth, differentiation survival	No defects in basal hematopoiesis
		IL-5	JAK2, STAT5	Th2 T cells	Eosinophil, B cells	Proliferation, activation	Decreased eosinophilia, defective CD5, B1 cell development
	γ _c -utilizing	IL-2	JAK1, JAK3, STAT5	T cells	T, B, NK cells, macrophages	Proliferation, cytotoxicity IFN-γ secretion, antibody production	Lymphoproliferation ^a
		IL-4 ^c	JAK1, JAK3, STAT6	Th2 T cells mast cells	T cell, B cell, macrophage	Proliferation, Th2 differentiation IgG1 and IgE production Inhibition of cell-mediated immunity	Defective Th2 differentiation and IgE production, decreased allergic responses
		IL-7	JAK1, JAK3, STAT5	Bone marrow, thymic stromal cells, spleen	Thymocytes, T cells, B cells	Growth, differentiation, survival	SCID ^a
		IL-9	JAK1, JAK3, STAT5	Th2 T cells	T cells, mast cell precursors	Proliferation	Not essential for Th2 pathology
		IL-15 ^c	JAK1, JAK3, STAT5	Many cells	T-cells, especially memory cells, NK cells	Proliferation, survival	Absence of NK and memory cells
		IL-21	JAK1, JAK3, STAT3	T cells, Th17 cells	T, B, and NK cells	Isotype switching, plasma cell differentiation, enhances CD8+ and NK cell responses, promotes Th17 cell differentiation	Acts in concert with IL-4 Decreased Th17 cells

Type II (Interferon)	Hetero-dimeric	IL-13	JAK1, TYK2, STAT6	Activated T cells	B cells, macrophage	Costimulator of proliferation, IgE increased CD23 and Class II, inhibits cytokine secretion and cell-mediated immunity	Defective Th2 responses and IgE production, decreased allergic responses
		IL-12	JAK2, TYK2, STAT4	Macrophages, DC, B cells	T cell, NK cell	Th1 differentiation, proliferation, cytotoxicity	Defective Th1 differentiation, susceptibility to bacterial infections ^a
		IL-23	JAK2, TYK2, STAT3, STAT5	Macrophages, DC	T cells,	IL-17 production	Reduced arthritis, inflammation,
		IL-35	?	Treg	T cells	Suppresses proliferation	Reduced Treg activity
		TSLP		Epithelial cells, keratinocytes	DC (human) B cells (mouse)	Th2 differentiation (human)	Shared receptor usage with IL-7R
	Heterodimeric	IFN- α/β	JAK1, TYK2, STAT1, STAT2	Plasmacytoid DC, Macrophages, fibroblasts, other	All, NK cell	Antiviral, antiproliferative increased MHC Class I activation	Susceptibility to viral infections ^a
		IFN- γ	JAK1, JAK2, STAT1	Th1 T cells NK cells	Macrophages, endothelium NK cells	Activation, increased MHC Class II expression, increased antigen presentation	Susceptibility to bacterial infections ^a
		IL-10	JAK1, TYK2, STAT3	Th2 T cells, other cells	Macrophages	Decreased MHC class II expression, decreased antigen presentation	Exaggerated inflammatory response and autoimmune disease
		IL-19, 20, 22, 24, 26	STAT1, STAT3	T cells, monocytes	T cells, keratinocytes	Induces production of inflammatory cytokines, Th2 responses	
IL-1/TLR		IL-28, 29, 30	STAT1, STAT2, STAT3, STAT4, STAT5	Many cells	Many cells	antiviral	
		IL-1 α/β	IRAK, MyD88, TRAF6, NF- κ B	Many cells, esp. macrophages	CNS, endothelial cell liver, thymocyte, macrophage	Fever, anorexia, activation acute-phase reactants co-stimulation, activation, cytokine secretion	Reduced inflammation, cooperates with TNF in host defense
		IL-1F, G					
		IL-18	IRAK, MyD88, TRAF6, NF- κ B				Increased susceptibility to infection, Reduced arthritis
		IL-33			T cells	Enhanced Th2 responses

Table 10.1 Cytokines classified by receptor families — Cont'd

Receptor family	Subfamily	Cytokine	Signaling	Source	Target	Action	Knockout phenotype
IL-17		IL-17A		Activated T cells	Endothelium, many cells	inflammation	Susceptibility to extracellular bacteria
		IL-17B,C,D		Many cells			
		IL-17E (IL-25)	TRAF2	mast cells Th2 cells	T cells	Enhanced Th2 responses	Increased susceptibility to helminths
		IL-17F		Activated T cells	Endothelium, many cells	inflammation	
TGF- β receptor serine kinase family		TGF β 1,2, 3		T cells, macrophages other	T cells, macrophages other	Inhibits growth and activation, promotes Th17	
Receptor tyrosine kinases		Stem cell factor	Ras/Raf/MAPK Stromal cell	Bone marrow	Pluripotent stem cell	Activation, growth	Defective hematopoietic stem cell proliferation, melanocyte production and development
		CSF-1 (M-CSF)	Ras/Raf/MAPK	Macrophage, endothelium, fibroblast, other	Committed myelomonocytic progenitors	Differentiation proliferation, survival	Monocytopenia, osteopetrosis, female infertility
		Flt-3 ligand	Ras/Raf/MAPK	Diverse Tissue	Myeloid cells, especially DC	Proliferation, differentiation	Reduced repopulating hematopoietic stem cells; reduced B-cell precursors
		IL- 32	NF- κ B, p38 MAPK	T, NK cells, monocytes, epithelia	monocytes	Induces TNF, IL-1, IL-6, IL-8	
		IL- 16		T and B cells, mast cells	CD4 T cells		
		IL-34	ERK	Many cells	Monocytes	Proliferation binds CSF-1 receptors	

^aHuman disease.^bIL17F is shared by these cytokines. In cases where STAT5a or STAT5b are designated, the cytokines appear to use either interchangeably.^cNote that two forms of the IL-4 and perhaps the IL-5 receptor exist.

Fig. 10.1 Schematic representation of prototypical receptors from each of the five major cytokine receptor superfamilies.

CLINICAL RELEVANCE

CLINICAL RELEVANCE OF TYPES I AND II CYTOKINE RECEPTORS

- >> IL-7R, γ c and Jak3 mutations cause SCID
- >> Tyk2 and Stat3 mutations cause Hyper IgE syndrome
- >> IL-12, IL-12R, and IFN γ R mutations are associated with susceptibility to intracellular infections
- >> Polymorphisms of IL-2R and IL-7R are associated with multiple sclerosis
- >> Polymorphism of IL-23R associated with inflammatory bowel disease
- >> Polymorphism of Stat4 associated with RA and SLE
- >> EPO, G-CSF, and TPO are used to treat cytopenias
- >> Anti-IL-2R mAb is used to prevent transplant rejection
- >> Anti-IL-12p40 is used to treat inflammatory bowel disease

IL-6 also serves as a major inducer of fever and the synthesis of acute-phase proteins (fibrinogen, serum amyloid A, haptoglobin, C-reactive protein, etc.) in the liver. The elevation of the erythrocyte sedimentation rate (ESR) in inflammatory disease largely reflects the accelerated synthesis of these proteins, and IL-6-deficient mice are defective in this response. Following exposure to IL-6, the liver reduces synthesis of albumin and transferrin and instead initiates hepatocyte regeneration. Other important functions of IL-6 include induction of adrenocorticotrophic hormone and anterior pituitary hormones such as PRL, GH and luteinizing hormone. IL-6 also plays a role in osteoporosis by affecting osteoclast function. For example, IL-6-deficient mice are protected from bone loss following estrogen depletion.

Unlike many cytokines, IL-6 can be detected in the serum, although baseline levels are low in the absence of inflammation. However, IL-6 is rapidly produced in response to bacterial and viral infections, inflammation, or trauma. Patients with rheumatoid arthritis, cardiac myxoma, Castleman's disease, and other autoimmune diseases have high serum levels of IL-6. This cytokine may also contribute to malignancies such as multiple myeloma.

IL-6 is produced by a range of cell types, but its expression in mononuclear phagocytes has been well documented. Stimulation of monocytes with IL-1, TNF, or LPS stimulates the expression of IL-6, whereas IL-4

and IL-13 inhibit its production. The promoter of the IL-6 gene contains a number of binding sites for the following transcription factors: nuclear factor- κ B (NF- κ B), nuclear factor for IL-6 (NF-IL-6, or CCAAT element-binding protein), activator protein-1 (AP-1), cAMP response element-binding protein (CREB), and the glucocorticoid receptor.

Interleukin-11

IL-11 and its receptor are widely expressed. It stimulates stem cells, megakaryocytes, myeloid precursors and erythroid precursors, as well as promoting B-cell differentiation. It also acts on nonhematopoietic cells, including bone and liver. IL-11 is induced by proinflammatory cytokines (IL-1, TNF) and by TGF- β .

Interleukin-27

IL-27, like IL-12, is composed of two subunits designated EBI3 and p28. It signals through a receptor comprising gp130 and WSX-1/TCCR (T-cell cytokine receptor), which is expressed on naïve CD4 T cells. IL-27 promotes Th1 differentiation but also has essential anti-inflammatory properties.⁷ It inhibits Th17 differentiation and enhances IL-10 production.

Interleukin-31

IL-31 is the most recently identified gp130-using cytokine. It is produced by Th2 cells. Overexpression of IL-31 results in atopic dermatitis.⁸

Cytokine receptors utilizing the β c chain

The cytokines IL-3, IL-5 and GM-CSF all bind to receptors that share a common β c receptor subunit (common β subunit). Each of the individual receptors for these cytokines also has a ligand-specific α subunit. Mice, but not humans, have a second β chain, β_{IL3} . This species-specific redundancy may explain why gene targeting of β c in the mouse did not result in loss of IL-3 responses, although β c-null mice did have reduced GM-CSF and IL-5 responses.

Interleukin-3

IL-3 binds to a receptor composed of a unique IL-3R α subunit and the common β c subunit. IL-3 synergizes with other cytokines to stimulate the growth of immature progenitor cells of all lineages, and is therefore

a multilineage colony-stimulating factor (CSF). It prevents cell death and promotes the survival of macrophages, mast cells, and megakaryocytes. IL-3 is produced mainly by lymphoid cells, but also by mast cells and eosinophils. IL-3-deficient mice have no obvious defect in hematopoiesis, suggesting that the major role of IL-3 *in vivo* may be in the response to stress, rather than to regulate hematopoiesis under normal conditions.

Interleukin-5

IL-5 is unusual among cytokines in that it is a disulfide-linked homodimer, with each component containing three α -helical bundles. Its major action is to promote the growth, differentiation, and activation of eosinophils. As such, it is very important in pathogenesis of allergic disease. IL-5^{-/-} mice fail to develop eosinophilia in response to parasitic or aeroallergen challenge. Remarkably, these mice exhibit minimal signs of inflammation and damage to the lungs. IL-5 deficiency does not affect the worm burden of infected mice, indicating that eosinophilia per se may not play an essential role in the host defense against helminths. Both IL-5 and IL-5R knockout mice have decreased numbers of CD5⁺ B cells (B-1 cells), concomitant with low serum concentrations of IgM and IgG₃. IL-5 is produced by activated helper T cells of the Th2 phenotype (see below), mast cells, and eosinophils in an autocrine manner.

Granulocyte-Macrophage-CSF

GM-CSF acts on hematopoietic precursors to support myelomonocytic differentiation. It also activates mature neutrophils and macrophages, increasing their microbicidal activity and inducing the production of proinflammatory cytokines. Along with IL-4 and IL-13, GM-CSF is a major stimulatory cytokine for the *in vitro* production of dendritic cells (DCs). Additionally, GM-CSF induces proliferation and activation of eosinophils and upregulates adhesion molecules on fibroblasts and endothelial cells. Homozygous inactivation of the GM-CSF gene in mice, however, does not affect steady-state hematopoiesis. Instead, these animals develop alveolar proteinosis and lymphoid hyperplasia, which is not due to a detectable infectious agent. β_c ^{-/-} mice also develop alveolar proteinosis, characterized by the accumulation of surfactant in the lungs. A similar defect may be responsible for disease in a subset of humans with this abnormality.

The production of GM-CSF can be induced by proinflammatory cytokines and LPS. Unsurprisingly, GM-CSF is made by activated lymphocytes, as well as other stimulated cells. GM-CSF is not ordinarily detectable in blood except under pathologic conditions such as asthma. GM-CSF has been used clinically to treat chemotherapy-induced neutropenia, especially in the context of certain infections (e.g., fungal). It has also been tested in myelodysplastic syndrome and aplastic anemia.

Cytokine receptors utilizing the γ_c chain

The cytokines IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all bind to receptors that share a common γ_c receptor subunit. The γ_c subunit and the ligand-specific subunits are expressed predominantly on lymphocytes, although they can be found on other hematopoietic cells as well. Accordingly, these cytokines might be expected to be important for the development and function of lymphoid cells. Proof of their importance

was provided when it was shown that mutation of the γ_c gene was responsible for X-linked severe combined immunodeficiency (SCID), which is characterized by a lack of T cells and NK cells, and poorly functioning B cells (Chapter 35).⁹ This disorder, which has proved to be the most common form of SCID in humans, is thus designated as a T-B⁺ SCID. Subsequently, γ_c knockout mice were found to also have a SCID phenotype, but one that differed from that of the human disorder. γ_c knockout mice also lack B cells, which points to species-specific functions of γ_c . The lack of γ_c abrogates signaling by all of the cytokines that utilize this subunit (IL-2, IL-4, IL-7, IL-9, IL-15 and IL-21), but the lack of IL-7 signaling is predominantly responsible for the SCID phenotype. Thus, the lesser importance of IL-7 signaling in human B-cell development probably explains the less severe block on B-cell function seen in patients with X-linked SCID.

Interleukin-2

The IL-2 receptor consists of three subunits, α , β and γ_c . The latter two are members of the type I cytokine receptor family. NK cells constitutively express these latter two subunits and respond to high doses of IL-2, whereas in T cells the IL-2R α subunit is induced upon activation, where it creates a high-affinity receptor for IL-2. IL-2R α is also inducible in activated monocytes and B cells. IL-2R α , however, is not a member of the type I cytokine receptor family. Rather, it resembles members of the complement family and IL-15R (see below). Thymocytes express high levels of IL-2R α , but a role of IL-2 in thymic development is not evident. For example, IL-2 and IL-2R α gene targeted mice exhibit normal thymocyte development.

IL-2, one of the first cytokines to be intensively studied, is produced principally by activated T cells and is a prototypical autocrine T-cell growth factor that is required for progression from the G1 to the S phase of the cell cycle in T cells activated *in vitro*. It is an important factor in determining the magnitude of T-cell and NK-cell responses, augmenting the cytolytic activity of T and NK cells and inducing IFN- γ secretion. IL-2 is also important in programming CD8 memory T cells, which undergo secondary expansion in viral infections.¹⁰ IL-2 is a growth factor for B cells and induces class switching. It also activates macrophages. Targeted deletion of the genes encoding IL-2, IL-2R α , and IL-2R β , however, yielded surprising phenotypes. T-cell development in these mice appears normal, but they succumb to autoimmune and lymphoproliferative disease, pointing to the existence of a separate, *in vivo* role of IL-2 whose function is to maintain lymphoid homeostasis and thus help prevent autoimmune disease.¹¹ IL-2-deficient mice develop massive enlargement of peripheral lymphoid organs, hemolytic anemia, inflammatory bowel disease, and infiltrative granulopoiesis. In addition, they have high levels of IgG₁ and IgE. Paradoxically, their T cells proliferate poorly *in vitro* in response to either polyclonal activators or antigen-specific signals. A similar phenotype is seen in humans with IL-2R α mutations.

Whereas the T-cell hyperplasia and tissue infiltration observed in IL-2 or IL-2R α chain-deficient individuals was originally thought to be due to a defect in the restimulation-induced cell death of activated T cells, abnormal regulatory T (Treg) cell function may provide an alternative mechanism (Chapter 16). Naturally arising Treg cells in both mice and humans express high levels of IL-2R α , and maintenance of peripheral Treg cell numbers has been shown to be dependent on IL-2.¹² In addition, IL-2 inhibits Th17 differentiation.

IL-2 is produced almost exclusively by activated T cells. It is rapidly induced upon recognition of foreign antigen. Indeed, IL-2 production is one of the key indicators of T-cell activation. The IL-2 promoter has been extensively characterized and contains binding sites for the following transcription factors: nuclear factor of activated T-cells (NFAT), AP-1, and NF- κ B. IL-2 production is also regulated by stabilization of its mRNA.

IL-2 has been used in a number of clinical circumstances both to treat malignancies and to boost CD4 T-cell counts in HIV. The clinical utility of IL-2 therapy is limited by its toxicity, two important manifestations being hepatic dysfunction and the so-called capillary or vascular leak syndrome. On the other hand, anti-IL-2R α monoclonal antibodies, daclizumab and basiliximab, are used to prevent rejection of allotransplants. Polymorphisms of IL-2R α are associated with multiple sclerosis.

Interleukin-4

As discussed above, two classes of IL-4R appear to exist.¹³ One consists of the IL-4R α subunit in conjunction with γ_c and is expressed on hematopoietic cells. The other, a 'type II' receptor, appears to consist of the IL-4R α subunit in association with the α chain of IL-13R. This latter receptor appears to be widely expressed. However, two IL-13R subunits have been cloned, so the exact composition of the type II IL-4R remains uncertain. The existence of two receptors helps explain why IL-4 has diverse actions on both hematopoietic and nonhematopoietic cells. The loss of IL-4R α would be predicted to block the actions of both IL-4 and IL-13, which could explain why gene targeting of IL-4R α leads to a more severe phenotype than that observed in IL-4-deficient mice. Polymorphisms of IL-4R α have been reported to be associated with a propensity towards atopy.¹⁴

In general, IL-4 serves to promote allergic response and to inhibit cell-mediated immune responses. Among the most important roles of IL-4 is its ability to promote differentiation of naive CD4 T cells into a subset that produces IL-4 and IL-5.^{15, 16} These cells are denoted the so-called Th2 (T-helper 2) subset, as opposed to Th1 cells, which produce lymphotoxin- α and IFN- γ (Chapter 17). In conjunction with CD40 activation, IL-4 also promotes B-cell proliferation and class switching, particularly to IgG₁ and IgE in mice and to IgG₄ and IgE in humans. Mice deficient in IL-4 have normal B lymphopoiesis and marked reductions in IgG₁ and IgE production in response to parasites. Importantly, these mice have residual Th2 responses, because IL-13, which also binds IL-4R α , can partially compensate for the defect.

IL-4 has also been shown to upregulate the expression of surface IgM, MHC class II, and CD23 on B cells. In conjunction with GM-CSF, it is also a growth factor for mast cells and basophils, as well as a potent inducer of DC differentiation. IL-4 inhibits macrophage activation and the production of proinflammatory cytokines. It antagonizes the effects of IFN- γ , blocks cytokine-induced proliferation of synoviocytes, down-regulates the expression of adhesion molecules, and antagonizes the induction of some acute-phase reactants in hepatocytes by IL-6.

IL-4 is made by the Th2 subset of CD4 T cells, basophils and mast cells. A minor population of NK1.1⁺ CD4 T cells also produces large amounts of IL-4. Based on the tight regulation of IL-4 production, the IL-4 promoter has received considerable attention. A number of transcription factors appear to be important in regulating IL-4 production, including NFAT, NF-IL6, C/EBP, c-MAF, and GATA-3. The IL-4 promoter has a Stat6 binding site, which is consistent with the fact that

IL-4 regulates its own expression. Epigenetic control and chromatin remodeling are also important aspects.¹⁷

Clinically, IL-4 has been tested in the treatment of malignancies and some autoimmune disorders. The ability of IL-4 to generate DCs is being exploited in the use of tumor vaccines. Conceivably, soluble IL-4R might also be useful in the treatment of allergic disease.

Interleukin-7

The IL-7 receptor consists of the IL-7R α chain (CD127) in association with γ_c . It is expressed on both immature and mature thymocytes. Humans with mutations of IL-7R α have T-B⁺ SCID, but unlike individuals with γ_c mutations, display normal NK cell development (Chapter 35).⁹

IL-7R α expression is tightly regulated during thymocyte development (Chapter 9). It is expressed in double-negative thymocytes, down-regulated in double-positive cells, and then re-expressed in single-positive thymocytes. It is also expressed in mature peripheral T cells. This suggests that IL-7 plays an important role in both developing thymocytes and mature T cells. This may be a reflection of its anti-apoptotic effects, which are attributable to the induction of Bcl-2 family members. IL-7 promotes the growth of thymocytes, as well as the expression and rearrangement of TCR genes and the expression of RAG1 and RAG2 (Chapter 4). IL-7R α is expressed on cutaneous T-cell lymphomas, which also produce this cytokine; thus the autocrine response to IL-7 may contribute to the growth of these tumors.

IL-7- and IL-7R-deficient mice exhibit impairments in both T- and B-cell development. Postnatal B-cell development in IL-7^{-/-} mice is blocked at the transition to pre-B cells and is arrested even earlier in IL-7R α ^{-/-} mice. This suggests that IL-7R α binds a cytokine other than IL-7, perhaps the thymic stroma-derived lymphopoietin. Why these abnormalities do not occur in humans with IL-7R α mutations is not clear: presumably a factor that does not bind IL-7R regulates this step in human B-cell development.

IL-7 is produced by a wide variety of cells, including marrow and perhaps thymic stromal cells, as well as in the kidney, spleen, epithelial cells and keratinocytes. This is consistent with its role in the maintenance of function in both immature and mature lymphocytes.

Clinically, IL-7 may be useful to restore immune function in some congenital immunodeficiencies, after bone marrow transplantation, or in HIV infection. Polymorphisms of the IL-7R are associated with multiple sclerosis.

Interleukin-9

IL-9 has some of the same properties as IL-4. It strongly synergizes with stem cell factor to promote the growth and differentiation of mast cells and is a potent regulator of mast cell function. IL-9 also potentiates IgE production induced by IL-4. Although it was first identified as a T-cell growth factor, a physiologic role in T-cell development has not been established. IL-9 is produced by activated Th2 cells. Some lymphoid tumors produce IL-9, where it may serve as an autocrine growth factor.

Interleukin-15

The IL-15 receptor consists of the IL-2R β and γ_c subunits in association with a unique ligand-specific subunit, IL-15R α , which is homologous to IL-2R α .¹⁸ These receptor proteins are not related to type I

cytokine receptors. Instead, they contain protein-binding motifs termed 'sushi domains'. The relatedness of these receptors and their cognate ligands is further emphasized by the fact that in both human and mouse they are physically linked in the genome. Not surprisingly, given their shared receptor usage, there are many similarities in the actions of IL-2 and IL-15, particularly in terms of the effects on lymphoid cells. Like IL-2, IL-15 induces proliferation and cytokine production in T and NK cells. However, despite the similarities between these two ligands/receptors there are a number of important differences. IL-15R α is more widely expressed than IL-2R α , IL-2R β and γ_c . In addition to lymphoid cells, IL-15R α is expressed in fibroblasts, epithelial, liver, intestine and other cells. IL-15 and IL-15R α knockout mice are defective in NK-cell production and in the generation of memory T cells, explaining the absence of NK development in patients with γ_c mutations.

The production of IL-15 is also very different from that of IL-2. IL-15 mRNA is expressed broadly in hematopoietic and nonhematopoietic cells, though it is not typically produced by T cells. HTLV-I-transformed T cells are an exception in that they produce abundant IL-15. Also in contrast to IL-2, IL-15 is not controlled predominantly at the level of transcription. Instead, there are multiple upstream AUGs in the 5' untranslated portion of the message that interfere with translation. A similar pattern of translational regulation is observed for IL-7 and IL-9, but is uncommon in other cytokine genes. IL-15 protein is also controlled at the level of secretion of the protein, but this is incompletely understood. High levels of IL-15 protein have been reported in synovial fluids from patients with rheumatoid arthritis, alveolar macrophages from patients with sarcoidosis, and peripheral blood mononuclear cells from patients with ulcerative colitis. Monoclonal anti-IL-15 antibody is being tested in rheumatoid arthritis.

Interleukin-21

IL-21 is a T cell-derived cytokine that works in concert with other γ_c cytokines. It synergizes with IL-7 and IL-15 to expand and activate CD8 T cells. IL-21 also augments the activity of NK cells. It further acts with IL-4 to activate B cells and induce class switching. IL-21 drives the differentiation of B cells into memory cells and terminally differentiated plasma cells.¹⁹ IL-21 is selectively produced by Th17s cells and promotes Th17 differentiation.

Other heterodimeric receptors

Interleukin-12

IL-12 is a heterodimer composed of two disulfide-linked polypeptide chains, p35 and p40, that are the products of two distinct genes.^{20,21} IL-12 p35 shares homology with other cytokines, such as IL-6, whereas p40 resembles the IL-6 receptor. Thus, IL-12 can be viewed as being synthesized as a ligand-receptor complex. Two chains of IL-12R have been identified. Because the ligand already comprises the α subunit, the two chains of the IL-12R are denoted IL-12R β_1 and β_2 . Expression of high-affinity IL-12R is very restricted, being found predominantly on T and NK cells. IL-12R expression is also notable in that it is regulated by the activation state of the cell. IL-12R β_1 and β_2 are highly inducible upon T-cell activation, and IL-4 inhibits IL-12R β_2 expression. This is important because IL-12R β_2 is required for IL-12 signaling and the activation

of the transcription factor Stat4. NK cells constitutively express IL-12R β_1 and IL-12R β_2 .

IL-12 plays a pivotal role in promoting cell-mediated immune responses. Humans with IL-12R mutations, as well as mice with IL-12 and IL-12R deficiency, have very blunted immune responses and are highly susceptible to infections by intracellular pathogens.²² An important function of IL-12 is that it promotes the differentiation of uncommitted helper T cells to the Th1 subset: i.e., T cells that produce LT- α and INF- γ . Th1 differentiation is markedly impaired in IL-12- and IL-12R-deficient mice. A major action of IL-12 is its ability to induce the production of IFN- γ , doing so synergistically in combination with IL-2 or IL-18. Consequently, many of the actions of IL-12 are blocked in IFN- γ or IFN- γ R knockout mice. IL-12 also induces proliferation and cytolytic activity of T and NK cells.

Dendritic cells and macrophages are the major producers of IL-12 in response to various pathogens, occupancy of Toll-like receptors and CD40. The IL-12p40 promoter is complex and contains NF- κ B sites, interferon response elements (IREs), and Ets binding sites. As with other cytokine genes, nucleosome remodeling is important in the regulation of IL-12.²³

Because of its profound effects on cell-mediated immunity, IL-12 has been used in a number of clinical circumstances. It has been used in the treatment of malignancies and infectious diseases, but its utility has been limited due to significant toxicity. IL-12 may also have use in vaccines as an adjuvant. Conversely, antagonizing the actions of IL-12 has been found to be useful in Th1-mediated diseases, including inflammatory bowel disease (Chapter 75).

Interleukin-23

IL-23 is another heterodimeric type I cytokine. It is composed of two disulfide-linked polypeptide chains, p19 and IL-12 p40. The IL-23 receptor also shares the IL-12R β_1 chain paired to the IL-23R.²⁴ The IL-23R complex is expressed on activated T cells. Its function relates to a third T lineage of differentiated helper cells, which produce high levels of the cytokine IL-17 (Th17, see below). IL-23 is thought to be important in the maintenance of Th17 cells. As such, IL-23 is thought to be important in host defense against extracellular bacteria and the pathogenesis of autoimmune and autoinflammatory disorders. It is notable in this regard that therapies that target IL-12p40 antagonize both IL-12 and IL-23. IL-23 is produced primarily by dendritic cells in response to TLR agonists. IL-23R polymorphisms are associated with inflammatory bowel disease, ankylosing spondylitis and other autoimmune diseases.

Interleukin-35

IL-35 is a newly described cytokine that is a dimer consisting of IL-12 p35 and EB13.

Interleukin-13

IL-13 has many of the same effects as IL-4 and shares a receptor subunit(s) with IL-4. IL-13-deficient mice have reduced levels of IL-4, IL-5, and IL-10. They also have lower IgE levels and eosinophilia. In mice deficient for both IL-4 and IL-13, these Th2 responses are abolished and the ability to clear parasites is severely impaired. These double-knockout mice default to Th1 responses, with concomitant production of INF- γ , IgG_{2a} and IgG_{2b}. Thus, it appears that IL-4 and IL-13 cooperate in promoting Th2 responses, having both overlapping and additive roles.

Thymic stromal lymphopoietin (TSLP)

TSLP is an IL-7-like cytokine expressed by epithelial cells and keratinocytes. Its receptor comprises TSLPR and IL-7R α , which is expressed primarily on monocytes and myeloid-derived dendritic cells, as well as on B cells. Curiously, this cytokine is reported to have different effects in mouse and human cells. TSLP-treated human dendritic cells promote Th2 differentiation.²⁵ In the mouse, TSLP contributes to B-cell development.

INTERFERONS

Type I interferons

The type I interferons include IFN- α , IFN- ω and IFN- β . There are at least 14 separate genes that encode structurally distinct forms of IFN- α , whereas IFN- β and IFN- ω are encoded by single genes. Nonetheless, each of these molecules binds to the same receptor, termed the IFN- α/β receptor. As a result, their actions are similar. Thus, it is unclear why there are so many distinct genes. Their relative potencies do differ; hence it is possible that these genes evolved in response to various viral pathogens. The duplication of IFN genes might also simply affect the magnitude of the antiviral responses. These intronless genes are all clustered on the short arm of chromosome 9 and appear to have diverged from a common ancestor more than 100 million years ago. The receptor is a heterodimer composed of two subunits termed IFNAR1 and IFNAR2. These subunits have limited similarity to type I cytokine receptors, although they lack the WSXWS motif.

A major effect of type I interferons is their antiviral action.²⁶ Discovered in 1957, they act on all cells to inhibit viral replication as well as cellular proliferation. A major mechanism is the inhibition of protein translation. They also upregulate MHC class I and downregulate MHC class II expression. IFN α/β increase the cytolytic activity of NK cells. Predictably, IFNAR1 knockout mice are extremely susceptible to infections, even though lymphoid development is normal.

Interferons are produced ubiquitously, viral infection being a major inducer of their transcriptional regulation. Type I IFN is also induced by intracellular bacterial pathogens and LPS. Immunoregulatory effects of IFN α/β are being increasingly recognized, and it is notable that a subset of dendritic cells produces very high levels.^{27,28} The promoter for IFN- β has been intensively analyzed. It binds a variety of transcription factors, including NF- κ B and interferon regulatory factor 1 (IRF-1). IRF-2 also binds to this promoter and functions as a repressor.

Type I IFN is used clinically in the treatment of certain infections, e.g., viral hepatitis. Owing to its antiproliferative action, it is also used in the treatment of certain malignancies, particularly hairy cell leukemia. IFN- β is used in the treatment of multiple sclerosis.

Newer interferon-like cytokines including IL-28A, IL-28B and IL-29 (also designated IFN- λ_1 , - λ_2 and - λ_3) have been identified. They bind to a receptor designated IL-28R. However, the exact *in vivo* functions of these interferon-like cytokines are poorly understood, although they probably contribute to antiviral responses.

Interferon- γ

IFN- γ is a major activator of macrophages. It enhances their ability to kill microorganisms by augmenting their cytolytic machinery. IFN- γ exerts this effect by causing the cell to increase its production of reactive oxygen

intermediates, including hydrogen peroxide, nitric oxide, and indoleamine dioxygenase. It also upregulates MHC class II expression. However, the activity of IFN- γ is by no means restricted to phagocytic cells. It has been shown to act on CD4 T cells to promote Th1 differentiation while inhibiting the generation of Th2 cells. It also promotes the maturation of CD8 T cells to cytotoxic cells. In mice, IFN- γ augments NK cytolytic activity, promotes switching to IgG_{2a} and IgG₃, and inhibits switching to IgG₁ and IgE. Endothelial cells and neutrophils are also activated by IFN- γ . Like IFN- α/β , IFN- γ also contributes to antiviral defenses.

The IFN- γ receptor is a heterodimer composed of IFN γ R α and IFN γ R β subunits. When one IFN- γ homodimer binds, a complex of two α and two β receptors is created.²⁹ Mice with a disrupted IFN γ R develop normally and have normal lymphoid development, but are highly susceptible to viral and bacterial infections, especially intracellular microbes. They have diminished macrophage MHC class II expression, decreased NK function, and reduced serum IgG_{2a} concentrations. Humans with mutations of IFN γ R subunits are also susceptible to mycobacterial and *Salmonella* infections.

The control of IFN- γ production is tightly regulated, T cells of the Th1 subset and NK cells being the major producers. Transcription factors including STAT4, T-bet, and Eomes, play an important roles in IFN- γ gene regulation.¹⁶ IFN- γ has been used to treat patients with immunodeficiencies (e.g., chronic granulomatous disease) and in certain patients with disseminated mycobacterial infections.³⁰ A monoclonal anti-IFN- γ antibody, fontolizumab, is being studied in the treatment of autoimmune disease.

Interleukin-10 and related cytokines

The major function of IL-10 is to serve as an anti-inflammatory and immunosuppressive cytokine. Unlike other cytokines in this family, it is a disulfide-linked dimer. A single IL-10R has been cloned, but the receptor may have additional components. The IL-10R is expressed on macrophages, mast cells, and most other hematopoietic cells. It is also inducible in nonhematopoietic cells by stimuli such as LPS.

IL-10 strongly inhibits the production of IL-1, IL-6, IL-8, IL-12, TNF, and other immune and inflammatory cytokines. It also inhibits macrophage antigen presentation and decreases expression of MHC class II, adhesion molecules, and the co-stimulatory molecules CD80 (B7.1) and CD86 (B7.2). The importance of IL-10 as an endogenous inhibitor of cell-mediated immunity is emphasized by the finding that IL-10-deficient mice develop autoimmune disease, which manifests with severe inflammatory bowel disease and exaggerated inflammatory responses. Delayed-type hypersensitivity and contact hypersensitivity responses are also prolonged and amplified in IL-10^{-/-} mice.

IL-10 is made by Th1 and Th2 cells, although a subset of T cells that preferentially produces IL-10 and TGF- β is sometimes denoted Th3. IL-10 is also produced by activated B cells, macrophages, keratinocytes, and bronchial epithelial cells. LPS and TNF are inducers of IL-10. IL-10 is readily detected in the blood of patients with septic shock and other inflammatory and immune disorders. Owing to its anti-inflammatory properties, IL-10 has been used experimentally in the treatment of some Th1-mediated autoimmune diseases. Paradoxically, IL-10 is elevated in patients with systemic lupus erythematosus, and there is a correlation between levels of IL-10 and autoantibody production.

There are viral homologs of IL-10 that may blunt the immune response to these pathogens. IL-10 also contributes to the immunosuppression

Fig. 10.2 Differentiation of T-helper cell subtypes.

seen in lepromatous leprosy or parasitic infestations. Other IL-10-related cytokines include IL-19, IL-20, IL-22, IL-24, and IL-26, but their biological actions are incompletely understood.³¹

Cytokines and the differentiation of T cells to helpers and effectors

Classically, precursor CD4 T-cell differentiation was viewed as polarization into one of two phenotypes: T-helper 1 (Th1) or T-helper 2 (Th2) (Fig. 10.2) (Chapter 16). More recently, other T-cell subsets have been identified, which will also be discussed. The key point is that differentiation into each of these subsets is regulated by different cytokines. Th1 cells drive the immune response towards cell-mediated immune responses, whereas Th2 cells promote a humoral or allergic response. The latter is protective against helminthic and other parasitic infestations. Th1 cells produce IL-2, LT- α and IFN- γ , whereas Th2 cells produce IL-4, IL-5 and IL-10. Both subsets produce IL-3.

The differentiation of helper T cells has important implications for host defense. In mouse models of parasitic disease, the failure of some strains to mount a Th1 response results in the majority of the animals succumbing to the infection. Conversely, in other disease models the production of a Th2 response results in enhanced survival, whereas a Th1 response causes more damage to the host. Although the mechanisms by which Th1 and Th2 development is governed are not fully understood, the cytokines themselves play important roles. Specifically, IL-4 promotes Th2 differentiation and antagonizes Th1 responses. Conversely, IL-12 and IFN- γ promote Th1 differentiation and antagonize Th2 development. A number of transcription factors have been reported to regulate this response. GATA-3, c-MAF and NFATp regulate IL-4 production and Th2 differentiation, whereas STAT4 and T-BET promote Th1 differentiation.^{16, 21}

The immunopathogenesis of autoimmune disease does not fit quite so neatly into the standard Th1/Th2 dichotomy. CD4 T cells can also

Fig. 10.3 The roles of JAKs and STATs in signal transduction by type I and II cytokine receptors.

differentiate into cells that produce IL-10 and transforming growth factor- β (TGF- β) – so-called Th3 cells – and can become ‘adaptive’ Treg cells; both types appear to protect against autoimmunity.³² As discussed above, IL-2 and TGF- β are important for Treg cell differentiation. Models of autoimmunity have pointed to the importance of yet another subset of Th cells that produces IL-17 and which are now termed Th17 cells. TGF- β and IL-6 are thought to promote Th17 differentiation from naïve progenitors, whereas IL-23 is important for the maintenance of these cells. In addition to a role in autoimmunity, IL-17 is important in host defense against extracellular bacteria.^{33, 34}

SIGNALING

Neither type I nor type II receptors exhibit intrinsic enzymatic activity. However, the membrane proximal segment of each of these receptors is conserved. This segment of the molecule serves as the site at which these receptors bind Janus kinases (JAKs), which play a pivotal role in signaling via this family of cytokine receptors (Fig. 10.3).

Janus kinases

Only four mammalian Janus kinases, JAK1, JAK2, JAK3, and TYK2, have been identified so far. JAKs are structurally unique, consisting of a C-terminal catalytically active kinase domain that is preceded by a segment termed the pseudokinase domain. The latter gives JAKs their name and has regulatory functions. A key feature of the JAKs is their association with cytokine receptors, which appears to be mediated by the N terminus. The utilization of the various JAKs by different cytokine receptors is summarized in Table 10.1.

Ligand binding to type I and II receptors induces the aggregation of receptor subunits, which brings JAKs in close proximity and allows them

to phosphorylate and activate each other. After activation, the JAKs phosphorylate receptor subunits on tyrosine residues, which allows the recruitment of proteins with SRC homology-2 (SH2) or phosphotyrosine-binding (PTB) domains. These proteins can also be phosphorylated by JAKs. Phosphorylation results in the activation of a number of biochemical pathways. Importantly, phosphorylation of cytokine receptors generates docking sites for a class of SH2-containing transcription factors termed the STATs (see below).

The pivotal function of the JAKs is vividly illustrated by mice or humans that are deficient in these kinases. The association of JAK3 with γ_c suggested that JAK3 mutations might also cause SCID, and indeed it was found that mutation of JAK3 results in autosomal recessive T^{B+} SCID (Chapter 35).³⁵ JAK3 knockout mice were also found to exhibit SCID. Indeed, mutation of either γ_c or JAK3 leads to the same functional defects. These findings led to the notion that a JAK3 inhibitor might represent a new class of immunosuppressant drug. One such inhibitor, CP 690,550, was effective in preclinical studies.³⁶ This drug is currently being tested in humans. Rarely, gain-of-function mutations of JAK3 occur in leukemia.

In contrast to JAK3-deficient mice and humans, gene targeting of *jak1* and *jak2* results in more diverse abnormalities. *Jak1*^{-/-} mice die perinatally from neurologic defects, but also have a SCID phenotype similar to *jak3*^{-/-} mice. This is explained by the fact that γ_c -containing cytokine receptors utilize JAK1 in association with their ligand-specific receptor subunit. Other cytokines that are dependent on JAK1 include those that use gp130 cytokine receptors (IL-6, LIF, OSM, CNTF, and IL-11) and type II receptors (IL-10, IFN- γ , and IFN- α/β). Gene-targeting of *jak2* was embryonically lethal, principally because JAK2 is essential for EPO function and the mice fail to form blood. In addition, JAK2 is necessary for signaling of other cytokines, including IL-3. The importance of the JAKs has been substantiated by the identification of chromosomal translocations in various leukemias resulting in TEL (a transcription factor)/JAK fusion proteins, which have constitutive kinase activity and uncontrolled signaling. For example, a mutation in the pseudokinase domain of JAK2 underlies most cases of polycythemia vera. Mutations of Tyk2 are associated with Hyper IgE syndrome.

STATs

Members of the signal transducer and activator of transcription (STAT) family of DNA-binding proteins serve a key role in transducing signals from cytokine receptors on the cell surface to the nucleus, where they regulate gene transcription. STATs are latent, cytosolic transcription factors that have SH2 domains (phosphotyrosine-binding modules) that allow them to be recruited to phosphorylated cytokine receptors (Fig. 10.3). Different STATs bind to specific cytokine receptors (Table 10.1). STATs are themselves tyrosine phosphorylated by JAKs, and this promotes their dimerization. STATs translocate to the nucleus, bind DNA, and regulate transcription.

There are seven mammalian STATs: STAT1, STAT2, STAT3, STAT4, STAT5a, STAT5b, and STAT6. *Stat* knockout mice document the essential and specific functions of these transcription factors in transmitting cytokine signals. *Stat1*^{-/-} mice develop normally, but have extreme susceptibility to viral and some bacterial infections, consistent with the defects seen in IFN γ ^{-/-} and IFN γ R^{-/-} mice, and in IFN β R-deficient humans. STAT1 also appears to be important in regulating apoptosis. Its absence is associated with tumorigenesis. Gene targeting of STAT3 leads

to early embryonic lethality, the lethality being related in part to interference with LIF function. Conditional knockouts of STAT3 in myeloid cells display exaggerated inflammatory responses, evidently due to a failure of IL-10 signaling. Stat3 is also essential for Th17 cells. Mutations of Stat3 underlie Hyper IgE syndrome. As might be expected from the fact that STAT4 is activated by IL-12; *stat4*^{-/-} mice develop normally but have defective cell-mediated immune responses and Th1 differentiation combined with augmented Th2 development. This phenotype is consistent with the abnormalities seen in IL-12^{-/-} mice, IL-12R^{-/-} mice, and IL-12R-deficient humans.

STAT6 is activated by IL-4. *Stat6*^{-/-} mice have defective Th2 development with defective IgE responses following infection with parasites. Lack of STAT6 dramatically attenuates allergic and asthmatic disease in animal models of these diseases. IL-13 also activates STAT6, and its responses are abrogated in *stat6*^{-/-} mice.

STAT5a and STAT5b are highly homologous, but nonetheless have different functions. *Stat5a*^{-/-} mice have impaired mammary gland development and failure of lactation, whereas *stat5b*^{-/-} mice have defective sexually dimorphic growth and growth hormone-dependent regulation of liver gene expression. *Stat5a/5b* doubly-deficient mice manifest increased perinatal lethality, decreased size, female infertility, and impaired lymphocyte development. *Stat5*^{-/-} mice develop lymphoproliferative disease reminiscent of IL-2- and IL-2R-deficient mice, presumably related to loss of Treg cells,

Attenuation of type-I and type-II cytokine signaling

Perhaps as important as the triggers that initiate signal transduction are the mechanisms for extinguishing the response.³⁷ There are several families of proteins involved in downregulating cytokine signaling. Among these are phosphatases, cytokine-inducible inhibitor molecules, and transcriptional repressors. The phosphatase SHP-1 interacts with cytokine receptors and downregulates signaling. *Mothaten* mice lack a functional SHP-1 protein and die at an early age from autoimmune disease.

Another family of proteins that attenuates cytokine signaling are the suppressors of cytokine signaling (SOCS), which are alternatively termed JAB, SSI, and CIS. These are SH2-containing proteins that bind to either cytokine receptors or to JAKs and inhibit signaling. There are at least eight members of this family. Largely due to systemic hyperresponsiveness to IFN- γ , SOCS-1^{-/-} mice die within a few weeks of birth. Another family member, SOCS-3, is important in controlling Th17 differentiation.³⁸

KEY CONCEPT

PROPERTIES OF THE TNF RECEPTOR SUPERFAMILY

- >> Activation of a TNF receptor can lead to a wide range of effects, from proliferation to apoptosis
- >> Transduction of signals through TRAFs leads to the enhancement of survival
- >> Signaling through death domains leads to the induction of apoptosis

CLINICAL RELEVANCE

TNFR SUPERFAMILY CYTOKINES AND RECEPTORS AND DISEASE

- >> Dominant mutations of TNFR1 are associated with autosomal dominant periodic fever syndromes known as TNFR1-associated periodic syndromes (TRAPS)
- >> Mutations in CD40L are associated with X-linked hyper-IgM syndrome (X-HIM)
- >> Dominant mutations in FAS are associated with autoimmune lymphoproliferative syndrome (ALPS)
- >> Rheumatoid arthritis often responds to therapeutic use of TNF antagonists

TNF RECEPTOR AND LIGAND SUPERFAMILIES

This large family of structurally related ligands, receptors, and inhibitory decoy receptors has various roles both within and without the immune system. The first two members of this family to be discovered were tumor necrosis factor (TNF) and lymphotoxin- α (LT α ; sometimes referred to as TNF- β). These molecules are secreted principally by activated myeloid and T cells. They have similar proinflammatory functions, but are only two members of a large family of related molecules that includes CD30, CD40, Fas ligand, and TRAIL. Indeed, the TNF family now contains more than 20 members, each of which appears to exhibit marked differences in tissue expression, ligand specificity and biological function (Fig. 10.4; Tables 10.2 and 10.3). This section describes general aspects of TNF and TNFR biology, with examples from three of the best-studied TNF-family members: TNF, lymphotoxin and Fas ligand.

LIGAND AND RECEPTOR STRUCTURE

Much of our understanding of the structural and functional characteristics of the TNF ligand and receptor superfamilies has been learned from analysis of TNF (TNFSF2), LT α (TNFSF1), FasL (TNFSF6), and their receptors. TNF and LT α are closely related homotrimeric proteins (32% identity). Human TNF is synthesized as a 233 amino acid glycoprotein. It contains a long (76 residue) amino-terminal sequence that anchors it to the cell membrane as a 25 kDa type II membrane protein. A secreted 17 kDa form of TNF is generated through the enzymatic cleavage of membrane-bound TNF by a metalloproteinase termed TNF- α -converting enzyme (TACE). Both soluble and membrane forms of TNF are thought to be noncovalent homotrimers held together by a trimerization domain in the secreted molecule. When bound, both forms of TNF are biologically active. They have different affinities for the two TNF receptors and thus may exhibit different biological properties (see below).

LT α differs from TNF in that it is synthesized as a secreted glycoprotein. Human LT α is synthesized as a 205 amino acid glycoprotein that in

native form exists as a 25 kDa homotrimer. It can bind both TNF receptors with affinities comparable to those of TNF, and has similar biological effects. However, a membrane-bound form of LT has been identified that consists of a heterotrimeric complex containing one LT α subunit noncovalently linked to two molecules of an LT α -related type II membrane protein termed LT β . The LT $\alpha_1\beta_2$ heterotrimer, also known as mLT, is not cleaved by TACE and is thought to exist exclusively as a membrane-bound complex. mLT does not bind either of the two TNF receptors, but rather exerts its effects on another member of the TNF receptor superfamily, the lymphotoxin β receptor (LT β R). TNF and the two LT subunits are encoded by closely linked single-copy genes situated in the class III major histocompatibility locus, at chromosome 6p21.3 in humans (Chapter 5).

The two receptors for TNF (and LT α) are type-I transmembrane glycoproteins. They are designated TNFR1 (also termed p60 in humans, p55 in mice, official designation TNFRSF1A) and TNFR2 (also known as p80 in humans, p75 in mice, TNFRSF1B). These receptors are characterized by cysteine-rich repeats of about 40 amino acids in their amino terminal extracellular domains. Each extracellular domain consists of three or four cysteine-rich regions containing four to six cysteines involved in intrachain disulfide bonds. The cytoplasmic domains of these receptors have no obvious similarity to any known kinase and are thought to lack intrinsic enzymatic activity. Signal transduction is therefore achieved by the recruitment and activation of adaptor proteins that recognize specific sequences in the cytoplasmic domains of these receptors. Recruitment of adaptor molecules activates a number of characteristic signaling pathways that can lead to a remarkably diverse set of cellular responses, including differentiation, activation, release of inflammatory mediators and apoptosis.

FAMILY MEMBERS AND THEIR ACTIONS

Tumor necrosis factor (TNF), lymphotoxin- α (LT α) and receptors

TNF is a major physiologic mediator of inflammation.³⁹ It initiates the response to Gram-negative bacteria that produce lipopolysaccharide (LPS). IFN- γ also induces TNF and augments its effects. TNF has been shown to induce fever, activate the coagulation system, induce hypoglycemia, depress cardiac contractility, reduce vascular resistance, induce cachexia and activate the acute-phase response in the liver. Thus, TNF is the major mediator of septic shock. TNF also upregulates MHC class I and class II expression, activates phagocytes, and induces mononuclear phagocytes to produce cytokines such as IL-1, IL-6, chemokines and TNF itself. Activation by TNF causes increased adhesion of cells to endothelium and can be cytotoxic, particularly to tumor cells. TNF-deficient mice are resistant to septic shock induced by high doses of LPS, but have increased susceptibility to bacterial infection. The dual role of TNF in controlling bacterial replication and in septic shock emphasizes the point that although the goal of immune response is to eliminate invading microorganisms, the response itself may be injurious to normal host tissues. Septic shock is an extreme example of this. Although the primary source of TNF is the mononuclear phagocyte, it is also produced by T cells, NK cells and mast cells. LT α shares many of the same biological effects as TNF, owing mainly to its ability to bind the same receptors. However, LT β R has been shown to play a unique role in the development of secondary lymph nodes.

Table 10.2 TNF superfamily ligands

Locus link ID	Symbol	Common name	Position	Aliases	Binds to receptor(s)	OMIM ID	Key Functions	Phenotype associated with over expression	Phenotype associated with deficiency	Human Genetic Diseases
4049	TNFSF1	Lymphotoxin alpha (LT α)	6p21.3	LT, TNFB, TNFSF1	TNFR2 (1B), TNFR1 (1A), HVEM (14)	153440	Lymphoid organ formation	Absence of LN and PP, defective GC formation		
7124	TNFSF2	Tumor necrosis factor (TNF)	6p21.3	DIF, TNFA, TNFSF2, CACHECTIN	TNFR2 (1B), TNFR1 (1A)	191160	Inflammation	Wasting syndrome, arthritis	defective GC formation, resistance to endotoxin shock and experimental arthritis	TNF2 (G-308A) polymorphism associated with increased susceptibility to septic shock, asthma and RA severity
4050	TNFSF3	Lymphotoxin beta (LT β)	6p21.3	p33, TNFC, TNFSF3	As a $\beta 2\alpha 1$ heterotrimer with LT α binds to LT β receptor (3)	600978	Lymphoid organ formation	Ectopic lymphoid organ formation		
7292	TNFSF4	OX40 Ligand	1q25	GP34, OX40L, TXGP1, CD134L, OX-40L	OX40 (4)	603594	CD4 T cell expansion, survival, and Th2 development	Increased Th2 responses	Th2 deficiency, blockade improves EAE	
959	TNFSF5	CD40 Ligand	Xq26	IGM, IMD3, TRAP, gp39, CD154, CD40L, HIGM1, T-BAM,	CD40 (5)	300386	Co-stimulation and differentiation of B cells and APC	Constitutive expression in B cells or keratinocytes leads to SLE-like syndrome	Immunodeficiency due to Defective Ig class switching and germinal center formation	X-linked hyper-IGM syndrome associated with CD40L loss of function mutations

Fig. 10.4 Schematic representation of members of the TNF ligand and receptor superfamily.

Fas ligand (FasL) and its receptor, Fas/APO-1/CD95

FAS (Apo-1/CD95/TNFRSF6) is a type I integral membrane protein that is structurally related to TNFR1. FAS is thought to trimerize and transduce proapoptotic signals upon binding of its ligand, FASL. Similar to TNF, the physiologic ligand for FAS (CD95L or FASL) is synthesized as a type II membrane protein and is expressed on activated B cells,

T cells and NK cells. FAS-induced apoptosis is thought to play an essential role in the termination of T-cell responses, particularly in the peripheral immune system. FAS also plays a key role in the induction of cell death by cytotoxic T cells (CTLs) and natural killer (NK) cells, where it functions in conjunction with perforin.

CD40

CD40 is expressed by a variety of cell types, including B cells, dendritic cells, monocytes, macrophages and endothelial cells. It plays a major co-stimulatory role in B-cell differentiation and recombination, and promotes survival through the induction of BCL-2 family members. Studies of CD40-deficient mice reveal that its function is not restricted to the humoral immune response, and that CD40 signaling also plays a role in cell-mediated immunity. CD40 ligand (CD154) is a 39 kDa protein expressed by activated CD4 T cells that can bind to and activate CD40 by cell-cell contact.

Other members

Other members of the TNFR family play various roles in the development and function of the immune system. CD40, OX-40, CD27, CD30, and 4-1BB can mediate co-stimulation of T-cell activation, albeit through different mechanisms. CD154 on T cells triggers antigen-presenting cell (APC) activation, including upregulation of the CD28 ligands B7-1 and B7-2. This indirectly boosts co-stimulation of the T-cell response. OX-40, CD27, CD30, and 4-1BB more likely act as direct co-stimulators of T-cell activation. The TNF family ligand BAFF (BlyS/TALL1/TNFSF13B) has a special role in B-cell maturation and can bind three distinct receptors, TACI (TNFRSF13B), BADD-R (TNFRSF13C), and BCMA (TNFRSF17).

SIGNALING

The TNF receptor superfamily can be divided into three subfamilies on the basis of the types of intracellular signaling molecules recruited, e.g., FADD, TRADD or TRAF⁴⁰ (Fig. 10.5). The cytoplasmic domains of several receptors, including TNFR1, FAS, DR3, DR4, and DR5, contain a conserved ~80 amino acid motif termed the death domain (DD). This element is required for recruitment of DD-containing adaptor molecules that are involved in the initiation of apoptotic cell death (see below). For this reason, these receptors have been termed 'death receptors.' The function of a number of death receptors may be regulated by decoy receptors, cell surface molecules that bind ligand, but lack functional intracellular domains. Other TNF receptor superfamily receptors that lack death domains (e.g., CD27, CD30, CD40, HVEM, TNFR2, LT-βR, OX-40, and 4-1BB) associate with different types of adapter molecules, most importantly members of the TRAF (TNFR-associated factor) family, as described below.

Death domains: TRADD and FADD

The primary molecule transducing signals in TNFR1 is TNF receptor-associated death domain (TRADD), which is directly recruited to TNFR1 after activation by TNF. The death domain mediates the interaction between TNFR1 and TRADD. This death domain motif is found in both adaptor molecules such as TRADD and the cytoplasmic domains

Fig. 10.5 The role of the death domain- and death effector domain-containing molecules in signaling by TNFR1 and TNFR2.

of the receptor itself (Fig. 10.5). The binding of TRADD to TNFR1 leads to the recruitment and activation of numerous associated signaling molecules. TNF-induced apoptosis is generally thought to be achieved by the interaction of TRADD with FADD (FAS-associated death domain; also known as MORT1), an ~27 kDa protein that oligomerizes with TRADD through the death domains contained in both molecules. In turn, recruitment of FADD coordinately activates several members of the caspase family.⁴¹ Caspases are cysteine aspartate proteases that are originally synthesized as zymogens. They are typically converted to their activated form by proteolytic cleavage, often by a distinct caspase upstream in the proteolytic cascade. Caspase-8, which is generally considered to be the apical caspase in the TNF and FAS pathways, is recruited to FADD in the activated complex. It is thought to be activated by a self-cleavage reaction. Cleaved caspase-8 can subsequently activate downstream caspases, notably caspase-3, which play a more proximal role in apoptosis. In addition to FADD, TRADD also has a TRAF-binding motif that leads to the recruitment of TRAF1 and 2 and the subsequent TRAF-dependent activation of proinflammatory signaling mediated by activation of NF-κB and MAP-kinase pathways. Although cell death in tumor cells can be induced by TNF, the most common result of TNFR1 ligation in primary immune cells is inflammation and sometimes protection from TNF-induced apoptosis. Recent evidence suggests that activation of pro-apoptotic and proinflammatory signaling by TNFR1 is not simultaneous, but proceeds by sequential steps. Ligation of receptor by TNF at the plasma membrane leads to immediate recruitment of the TRAF proteins. This is followed by receptor internalization and dissociation of TRADD from the receptor, and then by a delayed recruitment of FADD and caspase-8 at later time points by TRADD.^{42, 43}

Unlike TNFR1, FAS can directly recruit FADD to its cytoplasmic death domain, leading to the rapid formation of a death-inducing signaling complex (DISC), which contains FADD/MORT1 and caspase-8, thereby permitting activation of downstream caspases. The FADD death domain is recruited through interactions between charged residues in the death domains of FAS and FADD. Caspase-8 recruitment is accomplished through a structurally related domain termed the death-effector domain (DED). FADD DED contains two hydrophobic patches not present in the DD that are vital for binding to the death-effector domains in the prodomain of caspase-8 and for apoptotic activity.⁴⁴ Once bound to FADD, the proteolytic activity of caspase-8 is turned on, resulting in the cleavage of downstream substrates and the initiation of apoptotic events. How caspase-8 is maintained in a dormant state until ligation of the appropriate death receptor has been intensively studied. It has been found that oligomerization of caspase-8 is critical to activate its proteolytic activity.⁴⁵ FADD also has the ability to self-associate through separated domains in the DED. This self-association drives the formation of larger oligomers of FADD that are essential for pro-apoptotic activity.

The efficiency of apoptosis induction by death receptors is regulated at many levels. At the extracellular level, decoy receptors for FasL and TRAIL exist in the human genome. Unfortunately, their absence in mice has made it difficult to define their physiological role. The submembrane localization of FAS and TNFR1 can control signaling efficiency. The presence of receptors in lipid rafts appears to influence the efficiency of assembly of the primary signaling complex, enhancing NF-κB induction by TNFR1 and death induction by FAS.^{43, 46} For FAS, the presence of receptors in lipid rafts also correlates with apoptosis that cannot be blocked by BCL-2, which has been termed 'type-I' signaling.

Table 10.3 TNF superfamily receptors (receptors in italics have a C-terminal death domain)

Locus Link ID	Symbol	Common name(s)	Position	Aliases	Binds to ligand(s)	OMIM ID	Key functions	Phenotype associated with deficiency	Human Genetic Diseases
7132	TNFRSF1A	Tumor necrosis factor receptor 1 (TNF-R1)	12p13.2	FPF, p55, p60, TBP1, TNF-R, TNFAR, TNFR1, p55-R, CD120a, TNFR55, TNFR60, TNF-R-I, TNF-R55, MGC19588	TNF- α (2), L α (1)	191190	Mediates TNF-induced inflammation (and apoptosis in some cells)	resistance to TNF-induced arthritis models, resistant to endotoxin shock, Increased sensitivity to bacterial pathogens	Periodic fever syndrome (TRAPS) associated with heterozygous extracellular mutations

The recruitment and activation of caspase-8 may be another important regulatory step in FAS signaling. A cellular inhibitory protein, c-FLIP (CFLAR/FLAME/I-Flce, Usurpin/Casper/CASH), shares homology with caspase-8 but contains a functionally inactive caspase domain. c-FLIP can be recruited to the FAS signaling complex, blocking activation of caspase-8 when overexpressed. Overexpression of c-FLIP blocks B-cell apoptosis *in vivo* and leads to autoantibody production. However, endogenous levels of c-FLIP do not readily correlate with sensitivity to FAS-induced apoptosis, so the physiological role of this protein awaits mouse knockout studies. Additional molecules associating with FAS have been identified such as DAXX and FAP-1, but are not clearly present in the physiological DISC.

TRAFs

The cytoplasmic domains of many receptors in the TNFR superfamily, including TNFR2, CD30, and CD40, do not contain death domains. Instead, the cytoplasmic domains contain short peptide consensus sequences that enable recruitment of TRAF proteins, which are a different family of adaptor proteins. A separate consensus sequence has been identified for TRAF6 versus other TRAF proteins, and other mechanisms probably operate to maintain the specificity of TRAF recruitment. Structural studies have revealed a mushroom-like structure for the TRAF proteins, with a trimer of the three TRAF subunits stabilized by a stalk-like coiled-coil domain.

TRAF proteins activate NF- κ B and MAP-kinase pathways through recruitment and activation of protein complexes that activate these signaling cascades. The exact mechanisms by which this occurs are not yet clear, but recent studies have called attention to the ability of TRAF proteins to catalyze ubiquitination of target signaling complexes, which can function as an activating step. TRAF6, which mediates NF- κ B activation by a number of TNF-family receptors, associates with a protein complex that mediates K63-linked ubiquitination and activation of the inhibitor of κ B kinase (IKK) complex, which consists of two catalytic subunits, IKK α and IKK β and a regulatory protein IKK γ or NEMO.⁴⁷ Rather than causing degradation of IKK, K-63 linked ubiquitination activates kinase activity, leading to phosphorylation and degradation of I κ B (inhibitor of NF- κ B) and the release of active NF- κ B subunits. Active NF- κ B subunits translocate to the nucleus, where they regulate the expression of a wide variety of genes involved in the inflammatory response.

Some TNF-family receptors use other mechanisms to activate NF- κ B. For example, LT β receptor activates the IKK complex via the serine-threonine kinase NIK, which was initially identified through its ability to associate with TRAF2. A naturally occurring mouse mutation termed alymphoplasia (*aly*) is the result of a point mutation of NIK. *Aly/aly* mice lack lymph nodes and Peyer's patches, and also exhibit disorganized splenic and thymic structures. This mutation, and the phenotype of LT β R knockout mice, revealed the critical role of this receptor in normal lymph node development and the formation of 'tertiary' lymphoid tissue in inflammation.

When a single TNF-family ligand, such as TNF, binds both a death receptor (TNFR1) and a nondeath receptor (TNFR2), a number of mechanisms regulate receptor signaling and the cellular outcome. Rather than functioning in cell death, the physiological function of TNFR2 may be as a co-stimulator of lymphocyte proliferation.⁴⁸ This appears to be mediated by the direct interaction of TRAF2 with the cytoplasmic tail of

Fig. 10.6 Signaling by TNFRs

TNFR2, which leads to the activation of NF- κ B and other signaling pathways (Fig. 10.6). Under some circumstances, TNFR2 can enhance apoptosis induced by TNF. This may occur through cross-talk that enhances apoptotic signaling through TNFR1, most likely by decreasing the availability of TRAF2 to bind TNFR1.

CLINICAL RELEVANCE

Many studies have implicated TNF in the pathogenesis of the chronic inflammatory diseases rheumatoid arthritis (RA) and Crohn's disease (CD). Levels of TNF are highly elevated in the synovial fluid and the serum of patients with RA, as well as in the mucosa of patients with CD. This suggests that the proinflammatory effects of TNF might underpin the severe inflammatory symptoms observed in these diseases. Of particular relevance to RA, TNF inhibits the synthesis of proteoglycan and bone formation and stimulates resorption of proteoglycan and bone. In addition, TNF-overexpressing transgenic mice develop chronic inflammatory polyarthritic disease. These findings have prompted the development of specific TNF inhibitors, which are demonstrating great promise in the treatment of RA and CD. The two best-characterized of these inhibitors are a monoclonal anti-TNF antibodies (infliximab and adalimumab) and chimeric TNFR2-Fc proteins (etanercept and lenercept). Clinical studies of these compounds have demonstrated that they can induce striking improvement in RA patients (Chapter 52). Side effects of TNF-antagonism include increased incidence of infection, particularly with *Mycobacterium tuberculosis*, and an increase incidence of cancer.⁴⁹

Mutations of *TNFR1* are associated with autosomal dominant periodic fever syndromes⁵⁰ (Chapter 61). These patients have missense mutations in exons encoding the extracellular regions of *TNFR1* that are thought to affect normal *TNFR1* function, prompting the designation *TNFR1*-associated periodic syndromes, or TRAPS. Although the precise role of *TNFR1* has yet to be elucidated, patients with TRAPS typically have low serum levels of soluble TNF receptors that might normally serve to neutralize and control serum TNF levels. Clinical studies are in progress to test the potential efficacy of etanercept in controlling fevers in TRAPS patients.

The *in vivo* role of FAS signaling in the regulation of the immune system was confirmed when the naturally arising *lpr* and *gld* mouse strains were found to harbor homozygous mutations of Fas and Fas ligand, respectively. Both of these mouse strains are characterized by lymphadenopathy and splenomegaly due to the accumulation of unusual CD4⁺CD8⁻ T cells, as well as the production of autoantibodies. Subsequently, humans with heterozygous mutations in the FAS receptor were identified with similar symptoms and autoantibodies.⁵¹ In this disease, the autoimmune lymphoproliferative syndrome or ALPS, the FAS mutations act as dominant negative inhibitors of intracellular signaling, causing defective apoptosis in all carriers of FAS mutations and overt disease in a variable percentage of family members (Chapters 14 and 35).

The gene encoding CD40 ligand is defective in X-linked hyper IgM syndrome (X-HIM), a rare inherited disorder in which affected male children generate only IgM antibodies, many of which are autoantibodies (Chapter 34). Patients with X-HIM frequently suffer opportunistic infections, usually bacterial, and have an increased susceptibility to cancer. The physiologic role of the BAFF receptor in mouse B-cell development is illustrated by BAFF-R mutations in the A/WySnJ mouse, which lacks peripheral B cells. TACI knockout mice have hyperactive B cells, but in humans, dominant negative TACI mutations have been found in patients with common variable immunodeficiency affecting B-cell numbers and function, arguing that in humans TACI serves as a positive modulator of B cells.^{52, 53} Mutations of BLYS have also been found in humans with common variable immunodeficiency.^{54, 55}

KEY CONCEPT

PROPERTIES OF THE IL-1R/TLR FAMILY

- >> IL-1 plays a key role in fever and acute-phase responses
- >> IL-18 augments Th1 differentiation
- >> TLRs modulate proinflammatory signals in response to bacterial proteins

■ INTERLEUKIN-1/TOLL-LIKE RECEPTOR FAMILY ■

LIGAND AND RECEPTOR STRUCTURE

The IL-1/Toll-like family of receptors comprises at least 11 members, including the IL-1RI, IL-1RII, IL-1R-associated protein (IL-1RAcP), IL-18R, IL-18RAcP, IL-1Rrp2, IL-1RAPL, IL-33R(T1/ST2), TIGGIR, SIGGIR and the mammalian Toll-like receptors (TLR1–10).^{56, 57} The ligands for these receptors include IL-1, IL-18 and IL-1F5–10, IL-33 (IL-1F11).⁵⁸

FAMILY MEMBERS AND THEIR ACTIONS

Interleukin-1

There are two cell surface receptors for IL-1, type I (IL-1RI) and type II (IL-1RII). Both of these bind ligand (Fig. 10.4), but only IL-1RI transduces signals. The extracellular domain of IL-1RI has three immunoglobulin-like domains and a 200 amino acid cytoplasmic domain. Upon ligand binding IL-1RI associates with IL-1R accessory protein (IL-1RAcP), which is critical for the initiation of signaling. The IL-1RII cytoplasmic domain is extremely short and has been suggested to be a 'decoy' receptor, competing with IL-1RI for ligand binding and attenuating signaling. Both IL-1Rs are susceptible to proteolytic cleavage near the membrane surface. Therefore, they can be found as soluble proteins, functioning as another mechanism to 'buffer' IL-1 signaling. These soluble receptors are readily detectable in the circulation. Additionally, IL-1R associates with a second subunit, termed the IL-1R associated protein (IL-1Rap).

There are three members of the IL-1 gene family: two agonists, IL-1 α and IL-1 β , and one antagonist, IL-1 receptor antagonist (IL-1Ra). IL-1 α and IL-1 β are structurally similar and have similar actions, but they are regulated differently. IL-1 β is regulated at the level of stabilization of the mRNA and at the level of translation. Both IL-1 α and IL-1 β are synthesized as precursor proteins. The pro-form of IL-1 α has biological activity, whereas that of IL-1 β does not. Pro-IL-1 β remains in the cytoplasm until it is cleaved by caspase-1, otherwise known as IL-1 β -converting enzyme (ICE). It is then transported out of the cell. IL-1 α is thought to be processed by a calpain-like converting enzyme.

Principal functions of IL-1 include the induction of acute-phase protein synthesis, cachexia and fever. In fact, it was the first endogenous pyrogen to be identified. It induces the production of IL-6 and

chemokines, promotes hematopoiesis, stimulates adhesion of vascular leukocytes to endothelium, and has procoagulant effects. Unlike TNF, however, it does not induce cell death. The major source of IL-1 is mononuclear phagocytes, but other cells also produce it. IL-1RI^{-/-} and IL-1 β ^{-/-} mice have blunted fever responses to some (but not all) stimuli. This indicates that despite the impressive actions of IL-1, it evidently is redundant to some extent in febrile responses.

Interleukin-18

IL-18R was first designated IL-1Rrp (IL-1R related protein) before being recognized as the receptor for IL-18. Mice lacking IL-18R fail to bind or respond to IL-18. The receptor is expressed predominantly on T cells, B cells and NK cells. It associates with an accessory protein, IL-18RAcP. A major action of IL-18 is the induction of IFN- γ , a function it typically performs synergistically with IL-12. Indeed, the ability to induce IFN- γ was the basis of its original discovery. Accordingly, IL-18-null mice have deficiencies in IFN- γ production, NK cell activity and Th1 responses. IL-18 can also induce IL-4 and IL-13 production, indicating a somewhat broader range of action. IL-18-binding protein interacts with IL-18 and prevents association with IL-18R.

Other IL-1 family members

IL-33 (IL-1F11) signals via the IL-1 receptor-related protein ST2, also known as IL-33R, and induces Th2-associated cytokines, including IL-4 and IL-5.⁵⁷ SIGIRR is a negative regulator of Toll-like receptor–IL-1 receptor signaling.⁵⁹ Other IL-1R family members have not been well studied.

SIGNALING

Ligand binding to IL-1R, IL-18R, and TLRs results in NF- κ B activation (Fig. 10.7). These receptors all associate with the adapter protein MyD88. Notably, MyD88 has a C-terminal TIR domain and an N-terminal death domain. MyD88 allows the recruitment of IL-1 receptor-associated kinase (IRAK), which also has an N-terminal death domain. IRAK, in turn, permits the recruitment and activation of a member of the TNF receptor-associated factor (TRAF) family, TRAF6. This leads to the activation of the serine kinases TAB2, TAK1 and inhibitor of κ B kinases, IKK α and IKK β . With IKK γ or NEMO, these kinases phosphorylate I κ B, which leads to its degradation within proteasomes, freeing bound NF- κ B for nuclear translocation. Mice deficient in MyD88, IRAK, and TRAF6 have diminished responses to IL-1R/TLR family ligands. Other adapter molecules, including Mal and TRIF, are involved in TLR signaling.

CLINICAL RELEVANCE

Because of the importance of IL-1 in the pathogenesis of fever, it would be expected that agents that inhibit IL-1 would be therapeutically useful. Indeed, IL-1Ra, the naturally produced antagonist, has been studied in a variety of settings. It has been found to be efficacious in the treatment of rheumatoid arthritis. The drug anakinra is also effective in other autoimmune-inflammatory disorders, including Muckle-Wells disease, neonatal multi-system inflammatory disease, and Still's disease.^{60,61}

Fig. 10.7 Mechanism of signal transduction by IL-1R and related receptors.

INTERLEUKIN-17 RECEPTORS

Although their precise functions are incompletely understood, IL-17 and related cytokines are major inducers of inflammation and serve to recruit inflammatory cells.

LIGAND AND RECEPTOR STRUCTURE

The IL-17 receptor family is incompletely understood, but comprises at least five receptors, IL-17AR and IL-17BR (IL-17RH1), IL-17RL (receptor like), IL-17RD and IL-17RE, which are ubiquitously expressed.^{24,62} These receptors have a single transmembrane domain and exceptionally large cytoplasmic tails. The ligands in the IL-17 family include IL-17A-F, but the precise interactions between ligands and receptors have not been defined. A viral IL-17 homolog, designated HVS-13, is present in the herpes virus saimiri genome. Structurally, this family of cytokines forms cystine knots. In this respect, these cytokines are related to other, better-known cytokines such as nerve growth factor. IL-17 (IL-17A) is located on human chromosome 6 (mouse chromosome 1) and is produced by activated CD4 and $\gamma\delta$ T cells. Recent findings have suggested that CD4 T cells that preferentially produce IL-17 (Th17 cells) represent a distinct lineage of effector Th cells.⁶³

IL-17F is located adjacent to IL-17. Although it seems to be regulated in a similar manner, it may be more widely expressed than IL-17. Less well studied are IL-17B, IL-17C and IL-17D. All of these are thought to be expressed in a variety of nonhematopoietic tissues, although IL-17D is reported to be produced by CD4 T cells.

With respect to their biological actions, IL-17A and IL-17F are most intensively studied. These cytokines evoke inflammation largely by inducing the production of chemokines, G-CSF, and GM-CSF, with the

subsequent recruitment of polymorphonuclear leukocytes. IL-17 also induces production of matrix metalloproteinase by epithelial cells, which may be an important aspect of the proinflammatory effects. IL-17 family cytokines appear to be important in host defense against *Klebsiella pneumoniae* and *Mycobacterium tuberculosis*. Abundant data also point to pathogenic roles of IL-17A in models of immune-mediated disease and in human autoimmune disorders.

IL-17E, which is also known as IL-25, is produced by Th2 cells and mast cells. It evokes an inflammatory response characterized by overproduction of Th2 cytokines, mucus production, epithelial cell hyperplasia, and eosinophilia. This cytokine is essential for the elimination of helminthic parasites.^{64,65}

SIGNALING

Engagement of the IL-17 receptor activates MAP kinases and NF- κ B. Signaling via IL-25 is reported to be dependent upon the adapter molecule TRAF6. IL-17 acts synergistically with TNF.⁶⁶ The IL-17R associates with an adapter molecule called Act.

CLINICAL RELEVANCE

Many human diseases and animal models of autoimmune disease have been associated with increased levels of IL-17. The inflammatory effects of IL-23 and IL-17 also appear to be associated with malignant transformation.⁶⁷ Because of this, targeting IL-17 ligands and receptors could be a useful strategy.

RECEPTOR TYROSINE KINASES

LIGAND AND RECEPTOR STRUCTURE

Many growth factors, such as insulin and epidermal growth factor, utilize receptor tyrosine kinases (RTKs). Although most of these factors are not typically classified as cytokines, some are. These include CSF-1 (colony-stimulating factor-1 or M-CSF), stem cell factor (SCF, c-KIT ligand, or steel factor), platelet-derived growth factor (PDGF), and FLT3 ligand (FMS-like tyrosine kinase 3 ligand, FLT3-L). All of these have important hematological effects and tend to be included in discussions of cytokines. The structure of SCF and CSF-1 is similar to that of the cytokines that bind type I receptors, as they too form four α -helical bundles, even though their receptors are entirely distinct. The similarities in the three-dimensional structure points to a common evolutionary ancestor. It is therefore reasonable to define these factors as cytokines. The receptors in this subfamily typically have five immunoglobulin-like loops in their ligand-binding extracellular domains. The cytoplasmic domain contains a tyrosine kinase catalytic domain interrupted by an 'insert region' that does not share homology with other tyrosine kinases. This segment is used to recruit various signaling molecules.

FAMILY MEMBERS AND THEIR ACTIONS

Bone marrow stromal cells can synthesize stem cell factor (SCF, c-KIT ligand, or Steel factor) as either a secreted or a transmembrane protein. SCF is required to make stem cells responsive to other CSFs. SCF is widely expressed during embryogenesis and is also detectable in the circulation of normal adults. It has effects on germ cells, melanocytes, and

hematopoietic precursors, as well as important effects on the differentiation of mast cells. Naturally occurring mouse mutations of SCF (Steel) or its receptor (W) have been recognized for many years. These mice have defects in hematopoiesis and fertility, lack mast cells, and have absent coat pigmentation.

CSF-1, also known as monocyte-macrophage-CSF or macrophage-CSF (M-CSF), is a hematopoietic growth factor that supports the survival and differentiation of monocytic cells. It is produced by a wide variety of cells, including monocytes, smooth muscle cells, endothelial cells, and fibroblasts. M-CSF deficient mice manifest monocytopenia and osteopetrosis. IL-34 is a new cytokine that binds to the CSF-1 receptor. FLT3-L synergizes with other cytokines, including SCF, in inducing proliferation of hematopoietic precursors. FLT3-L is also an important regulator of dendritic cells.

SIGNALING

The first step in signaling by the RTKs is ligand-induced receptor dimerization (Fig. 10.8). Dimerization brings the two kinase domains into proximity and results in the activation of phosphotransferase activity. This leads to autophosphorylation of the receptor subunits on the tyrosine residues, which are then bound by a variety of signaling molecules, initiating signal transduction.⁶⁸ During this important step the signaling and adapter molecules recognize phosphotyrosine residues on the RTKs by virtue of either their SH2 (src homology 2) domains or their phosphotyrosine binding (PTB) domains.

A major pathway activated by RTKs is the RAS/RAF/ERK pathway. RAS is a small G protein with intrinsic low GDP/GTP exchange activity. In RTK signal transduction, two adapter proteins, GRB2 and SHC,

Fig. 10.8 Mechanism of signal transduction by receptor tyrosine kinases.

KEY CONCEPT

PROPERTIES OF THE TGF- β RECEPTOR FAMILY

- >> TGF- β receptors play a key role in lymphoid homeostasis, with pro- and anti-inflammatory actions
- >> TGF- β promotes the differentiation of regulatory T cells and Th17 cells.
- >> TGF- β receptors transduce signals through SMAD proteins
- >> TGF- β receptor function is dysregulated in many forms of human cancer

have important functions in RAS activation. In some cases, GRB2 binds directly to phosphotyrosine residues on the cytoplasmic tail of the receptor via its SH2 domain. Alternatively, SHC can bind first and then recruit GRB2. In addition to an SH2 domain, GRB2 has two SH3 domains that bind proline-rich segments of the guanine nucleotide exchange factor son of sevenless protein (SOS), recruiting it to the membrane and allowing it to activate RAS. Activated RAS binds and activates the serine/threonine kinase RAF, which in turn phosphorylates the dual-specificity kinase MEK. Activated MEK phosphorylates and activates ERK (extracellular signal-regulated kinase), which then translocates to the nucleus, where it phosphorylates and modulates the activity of various transcription factors, including ELK-1. Accordingly, mutations of RAS that lead to the constitutive activation of the ERK pathway have been found in a wide variety of human cancers.

Another important pathway activated by RTKs is the phosphatidylinositol 3'-OH kinase (PI3-kinase) pathway.⁶⁹ PI3-kinase catalyzes the formation of phosphatidylinositol-3,4,5-trisphosphate (PtdIns(3,4,5)P₃) and PtdIns(3,4)P₂. These phospholipids are recognized by proteins with pleckstrin homology (PH) domains. One such protein is protein kinase B (PKB or AKT), which has been implicated in the regulation of apoptosis. The PI3-kinase pathway is inhibited by the lipid phosphatase PTEN, which dephosphorylates PI3-kinase-generated phosphatidylinositides. Deletion of PTEN has been found in numerous tumor types, demonstrating a role for this protein as a tumor suppressor.

Gain-of-function mutations of *c-kit* result in a disorder termed systemic mastocytosis. Mutations resulting in a fusion between the *PDGFRA* and *FIP1L1* genes underlie hypereosinophilic syndrome.^{70,71}

TRANSFORMING GROWTH FACTOR- β LIGAND AND RECEPTOR FAMILIES

The transforming growth factor- β s (TGF- β) are a family of over 40 cytokines that inhibit cellular proliferation and can induce apoptosis of a variety of cell types. TGF- β s are involved in a number of biological processes, including tissue remodeling, wound repair, development, and hematopoiesis. Mutations of the elements in this pathway also contribute to malignant transformation. The mammalian ligands that belong to this family include TGF- β ₁, - β ₂, and - β ₃, bone morphogenic proteins (BMPs), activins, inhibins, and müllerian-inhibiting substance. Despite

the name, TGF- β s inhibit the growth of many other cells, and, in combination with other cytokines and growth factors, may induce growth instead. TGF- β s also induce collagen and fibronectin production by fibroblasts, which is thought to be responsible, at least in part, for diseases characterized by fibrosis (e.g., systemic sclerosis and pulmonary fibrosis). Functionally, TGF- β inhibits many aspects of lymphocyte function, including T-cell proliferation and CTL maturation. Transgenic mouse studies have been performed using dominant negative forms of the TGF- β receptor. These mice exhibit massive expansion of lymphoid organs and develop T-cell lymphoproliferative disorders, suggesting a critical role for TGF- β in T-cell homeostasis.³²

LIGAND AND RECEPTOR STRUCTURE

The TGF- β s are expressed as biologically inactive disulphide-linked dimers, which are cleaved to form active dimers. On translocation into the endoplasmic reticulum the N-terminal leader peptide is cleaved, and the mature protein is subsequently generated by a second cleavage event that releases an N-terminal pro-region. The pro-region can remain associated with the biologically active C-terminal region, inhibiting its activity.

The biological effects of the TGF- β s and their related ligands are mediated by two classes of receptor, designated type I (RI) and type II (RII).⁷² A third group of receptors, denoted type III, also exists (e.g., TGF- β RIII in the case of TGF- β). This latter group does not actively participate in signal transduction, but is thought to function to present ligands to the functional receptors. Similar to the RTKs described previously, the cytoplasmic domains of TGF- β receptors possess intrinsic kinase activity. However, TGF- β RI and TGF- β RII encode serine/threonine kinases. The signaling cascade appears to be initiated by the binding of TGF- β to the type II receptor, inducing the assembly of a ternary complex containing TGF- β , TGF- β RII, and TGF- β RI.

FAMILY MEMBERS AND THEIR ACTIONS

The three known human TGF- β s – TGF- β ₁, TGF- β ₂, and TGF- β ₃ – all have expressed molecular weights of 25 kDa. These three isoforms of TGF- β are closely related and have very similar biological functions. In humans the genes encoding TGF- β ₁, ₂ and ₃ are located at 19q13, 1q41 and 14q24, respectively. TGF- β ₁ is the most abundant form, and is the only isoform found in platelets. T cells and monocytes mainly synthesize TGF- β ₁, a critical function of which is to antagonize lymphocyte responses.

Approximately half of TGF- β ₁^{-/-} mice survive until birth, and 3–4 weeks later they typically succumb to an overwhelming autoimmune state characterized by lymphoid and mononuclear infiltration of the heart, lung, and other tissues, and by autoantibody production. These studies, along with selective inhibition of TGF- β function in T cells, indicate that TGF- β plays a crucial role in T-cell homeostasis and the prevention of spontaneous T-cell differentiation. TGF- β ₁ clearly has very complex actions, however: it induces FoxP3, promotes adaptive Treg cell differentiation, and inhibits IFN- γ production. Conversely, TGF- β ₁ with IL-6 induces IL-17, a proinflammatory cytokine. Thus, TGF- β ₁ has both proinflammatory and anti-inflammatory activities.

TGF- β ₂ is the most abundant TGF- β isoform in body fluids, whereas TGF- β ₃ is the least abundant of the three. TGF- β ₂ and TGF- β ₃ null mice exhibit defects distinct from those observed in TGF- β ₁ knockouts,

Fig. 10.9 SMADs and signaling by TGF- β superfamily receptor serine kinases.

particularly in bone and internal organ formation. Their deficiency is embryonically lethal, demonstrating that although the three isoforms functional similarly *in vitro*, they play distinct roles *in vivo*.

The human type II receptor is an 80 kDa glycoprotein which, as mentioned above, is the principal receptor for TGF- β . Upon binding of its ligand to RII, the type I receptor is recruited into the complex and activated through phosphorylation of its GS domain. The principal type I receptor in the TGF- β pathway is the ~55 kDa activin-like kinase-5 (ALK-5). ALK-1 can also be recruited into the complex and can transduce TGF- β -mediated signals.

SIGNALING

Ligand binding to the type II receptor allows the recruitment of the type I receptor (Fig. 10.9).⁷² Although the receptor subunits have some affinity for one another, the complex of the receptor subunits bound to ligand is more stable. The type II receptor is thought to be a constitutively active kinase. Upon ligand binding, the type II receptor phosphorylates the type I receptor. The type I receptor is structurally distinct from the type II receptor in having a juxtamembrane domain that precedes the kinase domain, which is referred to as the GS domain. It is this site that is phosphorylated by the type II receptor. In turn, the type I receptor is responsible for phosphorylating key signaling intermediates. It is not clear whether activation of the type I receptor is due to enhancement of its kinase activity, to the appearance of substrate-binding sites, or to a combination of the two.

SMADS

The primary substrates activated by the type I receptors are SMADs, a group of related proteins that have been highly conserved throughout evolution and play a critical role in TGF- β signal transduction.⁷³ Eight mammalian SMADs have been identified. All exhibit a high degree of

specificity for conserved motifs in the cytoplasmic tail of type I receptors. These proteins do not contain any previously known structural or enzymatic motifs. However, they have two homology domains, termed the MH1 and MH2 domains, at the N and C termini, respectively, which are separated by a central linker domain. The extreme C terminus of some SMADs is a critical site of phosphorylation, as described below.

SMADs have been subdivided into three classes based on functional distinctions. The receptor-regulated SMADs (R-Smads) directly interact with, and are phosphorylated by, the type I receptor. These include SMAD1, -2, -3, -5, and -8. Smad2 and Smad3 are phosphorylated in response to TGF- β , whereas Smad1, -5, and -8 are primarily activated in response to BMP activation. R-SMADs bind to the GS domain of type I receptor and are phosphorylated at a conserved SSXS motif in their C terminus. The interaction of R-SMADs with TGF- β receptors may also be regulated by another molecule termed SARA (SMAD anchor for receptor activation). SARA binds unphosphorylated SMAD2 and SMAD3. By virtue of its FYVE domain, SARA may bind phospholipids and localize SMADs to the plasma membrane, facilitating receptor binding. Phosphorylation of SMADs also permits dissociation from SARA.

Upon recruitment to their cognate activated type I receptor, R-SMADs are phosphorylated on C-terminal serine residues, triggering homodimerization of R-SMADs or heterodimerization with another class of SMAD, the common SMAD or C-SMAD. SMAD4 is the only known C-SMAD in vertebrates. It is thought to function as the central and essential downstream mediator of other SMADs in all TGF- β /BMP pathways. The SMAD MH2 domain is important for both receptor interaction and SMAD dimerization. However, SMAD4 lacks the SSXS element conserved in the R-SMADs and thus is not phosphorylated, rendering it unable to bind type I receptors directly.

The third subfamily of SMADs are the inhibitory SMADs or I-SMADs. In mammals, SMAD6 and SMAD7 are the I-SMADs. The I-SMADs may have different modes of function. For example, SMAD7 is induced by TGF- β and binds to TGF- β receptors inhibiting the phosphorylation of R-SMADs, thus serving as a classic feedback inhibitor. SMAD6 utilizes an alternative mechanism, and is thought to function by competing with SMAD4 for binding to an R-SMAD.

Consistent with their key functions in development, gene targeting of SMAD molecules has been shown to produce severe phenotypic abnormalities. SMAD2 null mice lack anterior/posterior specification and fail to develop mesoderm. SMAD3-deficient mice have limb malformations and defective immune function. SMAD3 null mice exhibit defective TGF- β responses. However, these mice also display accelerated wound healing compared to normal mice, which seems to contradict the role of SMAD3 as a positive regulator of TGF- β in enhancing wound healing. SMAD4-deficient mice die early in embryogenesis and exhibit severe defects in gastrulation. Of the I-SMADs, studies with SMAD6-deficient mice indicate a role in the development and homeostasis of the cardiovascular system.

Once phosphorylated, R-SMADs dissociate from the activated type I receptor and associate with SMAD4 in the cytoplasm. This is followed by nuclear translocation of the heteromeric SMAD complex, the binding to cognate DNA motifs in the promoters of TGF- β -responsive genes, and the concomitant induction of transcription. The SMAD MH1 motif mediates sequence-specific DNA binding, whereas the MH2 domain contains the transcriptional activation domain.

Other TGF- β -activated pathways

Although a canonical SMAD DNA-binding element (SBE) has been described (AGAC), comparison of the TGF- β responsiveness of synthetic promoters to natural promoters has revealed that SMADs can only partially account for the gene-regulatory effects of TGF- β signaling. SMADs also interact with a variety of other transcription factors, transcriptional co-activators, and transcriptional co-repressors to coordinately regulate transcription of a select subset of complex promoters. For example, FAST-1 (forkhead activin signal transducer), a winged helix forkhead transcription factor, associates with the SMAD2/SMAD4 complex. Moreover, SMADs also bind to c-JUN/c-FOS, and AP-1 sites frequently overlap with SBE sites in the naturally occurring promoters of TGF- β -responsive genes. SMADs can also bind ATF2, the vitamin D receptor, and other transcription factors, and can recruit the co-activators CBP/p300. Additionally, the SKI and SNON co-repressors can interact with SMADs and antagonize TGF- β signaling.

Other signaling pathways are known to mediate TGF- β signals. In particular, a number of members of the mitogen-activated protein kinase (MAPK) family are activated in response to TGF- β . TGF- β induces ERK, JNK and p38 MAPK activity. Inhibition of several of these pathways inhibits TGF- β -mediated transcriptional activation. In addition, a mitogen-activated protein kinase kinase kinase family member, TAK1 (TGF- β -associated kinase-1), has been implicated in TGF- β signaling. TAK1 is activated in response to ligand binding and has been shown to associate with another molecule, TAB1 (TAK1-associated binding protein), which activates TAK1 kinase activity. Together, they have been reported to activate the MAPK pathway(s), leading to activation of p38/MPK2 and c-JUN N-terminal kinase (JNK), with evidence that this may take place via MKK6 and MKK4, respectively.

CLINICAL RELEVANCE

Although the relevance of TGF- β to clinical immunology remains unclear, defects in the TGF- β pathway have been identified in a range of human cancers. SMAD4 is deleted in half of all human pancreatic carcinomas. Mutations in SMAD2 have been identified in patients with colon cancer, and somatic mutations in TGF- β receptors have been identified in colon and gastric cancers. Loss of SMAD3 is associated with leukemia. In addition, oncogenic RAS has been shown to repress SMAD signaling by negatively regulating SMAD2 and SMAD3.

OTHER CYTOKINES

Several new cytokines have been identified, but their functions are less clear than those of the other cytokines discussed above. IL-16 was formerly termed lymphocyte chemoattractant factor, because of its ability to recruit CD4 T cells.⁷⁴ It is unrelated to other cytokines and its only known receptor is the CD4 molecule. It was originally identified as a product of CD8 T cells, but its message is widely expressed. CD4 T cells, eosinophils and mast cells can all secrete IL-16. It is present in broncho-alveolar lavage fluids from asthmatics and sarcoid patients. It has also been detected in blister fluid from bullous pemphigoid lesions. The physiologic function of IL-16 has yet to be clarified.

IL-32 is one of the newest cytokines and it too is structurally distinct.^{75,76} It is inducible by the combination of IL-12 and IL-18. IL-32

induces the expression of various cytokines, including TNF, IL-1, IL-6 and chemokines, and can synergize with muramyl dipeptides. IL-32 signals via NF- κ B and p38. IL-32 is present in rheumatoid synovium, and injection of IL-32 induces inflammation and recruitment of inflammatory cells.

IL-14 was identified as a high molecular weight B-cell growth factor produced by T cells and some B-cell tumors. The precise nature of this putative cytokine is still uncertain.

CONCLUSIONS AND SUMMARY

Cytokines encompass a wide range of molecules that are essential for communication between cells of the immune system and other nonimmune cells. Although the number of cytokines already seems vast, it is likely that more will be discovered in the future. Considerable progress has been made in defining the *in vivo* functions of various cytokines. Equally impressive have been advances in our understanding how dysregulation of cytokines and cytokine signaling contributes to human disease. Cytokine and anti-cytokine therapies are being successfully used in the clinic, and it is likely that their use will increase with advances in the understanding of the immunobiology of these cytokines.

Chemokines and chemokine receptors

Philip M. Murphy

11

The chemokines are a family of *chemotactic cytokines* that coordinate leukocyte trafficking and activation [in the immune system]. Chemokines normally promote host defense and repair, but may also regulate non-immunological processes, such as organ development and angiogenesis. They can also be used to promote detrimental processes such as cancer and autoimmunity. Chemokines act by binding to G protein-coupled receptors, two of which, CCR5 and CXCR4, are exploited by HIV for target cell entry. This chapter describes the basic principles and clinical correlates of chemokine regulation of the immune system.

KEY CONCEPTS

Chemokine and chemokine receptor properties

- >> **Definition** Chemokines, the largest subgroup of cytokines, are defined by structure, not function; chemokine receptors are defined by function not structure.
- >> **Evolution** Chemokines and chemokine receptors arose in vertebrates, and have been copied or mimicked by many poxviruses, herpes viruses and retroviruses.
- >> **Ligand-receptor promiscuity** Chemokines usually bind more than one receptor subtype. Chemokine receptors usually bind more than one chemokine, but from a single chemokine subclass.
- >> **Cell biology** Chemokines coordinate leukocyte trafficking but may have prominent nontrafficking functions (e.g., lymphocyte proliferation/apoptosis/differentiation/activation, granulocyte degranulation/superoxide production, direct antimicrobial activity), as well as effects on other cell types in nonimmunologic contexts (e.g., development, cancer, angiogenesis).
- >> **Biology** Chemokines act redundantly or nonredundantly *in vivo*, depending on the context. Host chemokine receptors mediate antimicrobial defense, but certain pathogens (e.g. HIV) can exploit chemokine receptors to infect the host. Moreover, excessive or inappropriate chemokine expression may pathologically amplify immunologically mediated disease.

■ MOLECULAR ORGANIZATION OF THE CHEMOKINE SYSTEM ■

CHEMOKINES

Chemokines are found in vertebrates from teleost fishes to humans. Copies of vertebrate chemokine genes are also found in many herpes viruses and poxviruses. Defined by structure, not by function, there are at least 45 unique human chemokines, which makes them the largest family of cytokines. Most chemokines are 66–111 amino acids long. All occupy a common sector of sequence space bounded loosely by ~20% identity for any pairwise comparison. Tertiary structure is highly conserved, partly because the disulfide-bonded cysteines are conservatively spaced (Fig. 11.1). Chemokines are subclassified according to variations in cysteine number and location. All have at least two cysteines, and all but two have at least four (Tables 11.1 and 11.2). In the four-cysteine group, the first two are either adjacent (CC motif, $n=24$) or separated by either one (CXC motif, $n=16$) or three (CX3C motif, $n=1$) non-conserved amino acids. The C chemokines ($n=2$) have only two cysteines, corresponding to C-2 and C-4 in the other subgroups. Disulfide bonds link C-1 to C-3 and C-2 to C-4. The conserved chemokine fold contains three β sheets arranged in the shape of a Greek key, overlaid by a C-terminal α -helical domain and flanked by an N-terminal domain that lacks order.¹ Sequence identity is <30% between members of different groups, but ranges from ~30% to 99% among CC and CXC chemokines considered separately. The group names are used as roots, followed by the letter 'L' and a number (e.g., CXCL1) in a systematic nomenclature that was established to resolve competing aliases.²

CC and CXC chemokines can be subclassified by additional motifs. The seven CXC chemokines with Glu-Leu-Arg (ELR) N-terminal to C-1 are >40% identical, attract neutrophils, bind the receptor CXCR2, and are angiogenic (Table 11.1). Among CXC chemokines lacking ELR, only CXCL12 is angiogenic and attracts neutrophils. CXCL9–11 also are >40% identical and share a receptor (CXCR3), but are angiostatic rather than angiogenic.

Class						Names	N	
CX3C:	CXXXC		C		C	CX3CL1	1	
Non-ELR CXC:	CX	C	C	C	C	CXCL#	9	
ELR CXC:	ELR	CX	C	C	C	CXCL#	7	
4C CC:	C	C	C	C	C	CCL#	19	
6C CC:	C	C	C	C	C	C	CCL#	5
C:	C				C	XCL#	2	

Fig. 11.1 Chemokine classification and nomenclature. Chemokine classes are defined by the number and arrangement of conserved cysteines, as shown. Brackets link cysteines that form disulfide bonds. ELR refers to the amino acids glu-leu-arg. X refers to an amino acid other than cysteine. The underscore is a spacer used to optimize the alignment. The N and C termini can vary considerably in length (not illustrated). For molecules with four cysteines, there are approximately 24 amino acids between Cys-2 and Cys-3 and 15 amino acids between Cys-3 and Cys-4. At right are listed the nomenclature system and the number of human chemokines known in each class (N).

Two cysteine-defined CC subgroups exist. Both have two additional cysteines (a total of six), with one in the C-terminal domain. They are distinguished by the location of the sixth cysteine, which can be found either in the C-terminal domain or between C-2 and C-3. CXCL16 and CX3CL1 cross classes to form a unique multimodular subgroup. Each has a chemokine domain, a mucin-like stalk, a transmembrane domain, and a C-terminal cytoplasmic module. Each can exist as either a membrane-bound or a shed form, enabling either direct cell–cell adhesion or chemotaxis, respectively.

Chemokine monomer, dimer and tetramer structures may occur. Complex quaternary structures bound to glycosaminoglycans (GAGs) on the surface of cells may also be important for function *in vivo*.¹ A native heterodimer composed of CCL3 and CCL4 subunits has been purified from activated human monocytes and peripheral blood lymphocytes.

CHEMOKINE RECEPTORS

Chemokine receptors are defined as mediators that activate cellular responses upon binding chemokines. All 19 known human subtypes are members of the seven-transmembrane (7TM) domain superfamily of G protein-coupled receptors.³ Chemokine-binding, membrane-anchoring and signaling domains come from a single polypeptide chain. Homo- and heterodimers have been reported, but the physiologic form has not been clearly delineated.

The ligand–receptor relationship is typically promiscuous, but chemokine subgroup restricted (Table 11.3). A systematic receptor nomenclature formula exploits this as follows: receptor name = ligand subgroup root + R (for ‘receptor’) + number in order of discovery. An exception is the C chemokine receptor XCR1, where ‘X’ distinguishes it from CR1, the previously assigned name for complement receptor 1. For consistency, the XCR1 ligands are named XCL1 and XCL2.

Each chemokine has a unique receptor specificity profile. Conversely, each receptor has a unique chemokine specificity profile. Almost all chemokines are chemotactic agonists, and a few are both agonists at one receptor and antagonists at another. Differential receptor usage and differential regulation of expression may account for nonredundant function *in vivo* observed for chemokines acting at the same receptor.

KEY CONCEPTS

Immunologic classification of the chemokine system

- >> **Homeostatic system** Constitutively expressed ligands and receptors. Important in hematopoiesis and immune surveillance. Key receptors: CXCR4 on hematopoietic progenitors; CXCR5 on naïve B cells; CCR7 on mature dendritic cells and naïve T cells; and gut and skin-specific T-cell homing receptors CCR9 and CCR10, respectively.
- >> **Inflammatory system** In innate immunity, inducible ligands and constitutively expressed receptors (e.g., neutrophil CXCR2, macrophage CCR2, eosinophil CCR3, and NK cell CX3CR1). In adaptive immunity, inducible ligands and inducible receptors (e.g., CXCR3 and CCR4 on Th1 and Th2 CD4+ T cells, respectively).
- >> **Decoy receptors** Some membrane proteins that bind chemokines do not signal and act instead as scavengers/ ‘decoy receptors’ to limit chemokine action.

ATYPICAL CHEMOKINE SYSTEM COMPONENTS

Three human 7TM proteins (Duffy, D6 and CCX CKR) bind chemokines promiscuously but do not signal, and may function as scavengers.⁴ Several endogenous nonchemokine ligands bind chemokine receptors, including aminoacyl tRNA synthetases and β defensin 2, possibly linking innate to adaptive immunity. In addition to chemokines, herpes viruses and pox viruses encode structurally related 7TM chemokine receptors, structurally unique chemokine-binding proteins (scavengers), and nonchemokine chemokine receptor ligands (agonists or antagonists). HIV also encodes chemokine mimics gp120 and tat. Viral chemokine elements may function to evade the immune system, to recruit new target cells, to reprogram gene expression for cell proliferation and angiogenesis, and for target cell entry.⁵

IMMUNOLOGIC CLASSIFICATION

Chemokines and chemokine receptors have differential leukocyte specificity, but together cover the full spectrum of leukocytes and populate two main subsystems, homeostatic and inflammatory (Table 11.4). Homeostatic

Table 11.1 The human CXC, CX3C and C chemokine families

ELR motif	Chemokine	Common aliases	Main source	Main immunologic roles	Chromosomal location	
ELR+	CXCL1	GRO α MGSA	Inducible in most hematopoietic and tissue cells Many tumors	Neutrophil trafficking	4q21.1	
	CXCL2	GRO β				
	CXCL3	GRO α				
ELR-	CXCL4	PF-4	Preformed in platelets	Procoagulant	4q21.1	
ELR+	CXCL5	ENA-78	Induced in epithelial cells of gut and lung; N, Mo, Plts, EC	Neutrophil trafficking		
	CXCL6	GCP-2	Induced in lung microvascular EC; Mo; alveolar epithelial cells, mesothelial cells, EC and M ϕ			
	CXCL7	NAP-2	Preformed in platelets			
	CXCL8	IL-8	Induced in most cell types			
ELR-	CXCL9	Mig	Induced in PMN, M ϕ , T cells, astrocytes, microglial cells, hepatocytes, EC, fibroblasts, keratinocytes, thymic stromal cells	Th1 response		
	CXCL10	IP-10	Induced in ECs, Mo, keratinocytes, respiratory & intestinal epithelial cells, astrocytes, microglia, mesangial cells, smooth muscle cells			
	CXCL11	I-TAC	ECs, Mo,			
	CXCL12	SDF-1, PBSF	Constitutive in bone marrow stromal cells; most tissues	Myelopoiesis HPC, neutrophil homing to BM B lymphopoiesis		10q11.21
	CXCL13	BCA-1	Constitutive in follicular HEV of secondary lymphoid tissue	Naïve B- and T-cell homing to follicles B1 cell homing to peritoneum Natural Ab production		4q21.1
	CXCL14	BRAK	Constitutive in most tissues, breast and kidney tumors	Macrophage migration	5q31.1	
ELR+	(CXCL15)	(mouse only)	Constitutive in lung epithelial cells	Neutrophil trafficking	NA	
ELR-	CXCL16	Sexckine	Constitutive in spleen; DCs of the T zone	T cell and DC homing to spleen	17p13	
NA	CX3CL1	Fractalkine	EC, neurons, Mo, DC	NK, Monocyte, M and Th1 cell migration	16q13	
	XCL1	Lymphotactin α	Epidermal T cells, NK, NK-T, activated CD8+ and Th1 CD4+ T cells	CD62L ^{lo} T effector cell migration	1q24.2	
	XCL2	Lymphotactin β				

NA, not applicable. Mo, monocyte; PMN, neutrophil; DC, dendritic cell; EC, endothelial cell; HEV, high endothelial venule; MPC, myeloid progenitor cell; plt, platelet; M ϕ , macrophage; GRO, growth-related oncogene; PF-4, platelet factor-4; GCP, granulocyte chemoattractant protein; ENA-78, 78 amino acid epithelial cell-derived neutrophil activator; NAP, neutrophil activating protein; IL-8, interleukin-8; Mig, monokine induced by IFN- γ ; I-TAC, interferon-inducible T-cell α chemoattractant; SDF, stromal cell-derived factor; BCA, B cell-activating chemokine; BRACK, breast and kidney associated chemokine.

Table 11.2 The human CC chemokine family

Chromosomal location	Chemokine	Common aliases	Sources	Main immunologic roles
17q11-12	CCL1	I-309	Inducible in Mo and CD4+ and CD8+ $\alpha\beta$ and CD4-CD8- $\gamma\delta$ T cells	Th2 response
	CCL2	MCP-1	Inducible in Mo, fibroblasts, keratinocytes, EC, PMN, synoviocytes, mesangial cells, astrocytes, lung epithelial cells and M Φ . Constitutively made in splenic arteriolar lymphatic sheath and medullary region of lymph node, many tumors, and arterial plaque EC.	Innate immunity Th2 response CD4+ T cell differentiation
	CCL3	MIP-1 α LD78 α MIP-1 α S	Inducible in Mo/M Φ , CD8+ T cells, B cells, plts, PMN, Eo, Ba, DC, NK, mast cells, keratinocytes, fibroblasts, mesangial cells, astrocytes, microglial cells, epith cells	Innate immunity Th1 response CD4 T cell differentiation
	CCL3L1	LD78 β MIP-1 α P	Similar to CCL3	Probably similar to CCL3
	CCL4	MIP-1 β	Similar to CCL3	Innate immunity Th1 response
	CCL5	RANTES	--Inducible in EC, T cells, epithelial cells, Mo, fibroblasts, mesangial cells, NK cells --Constitutively expressed and stored in plt and Eo granules	Innate immunity Th1 and Th2 response
NA	(CCL6)	Mouse only	Inducible in bone marrow and peritoneal-derived M Φ	ND
17q11-12	CCL7	MCP-3	Inducible in Mo, plts, fibroblasts, EC, skin, bronchial epithelial cells, astrocytes	Th2 response
	CCL8	MCP-2	Inducible in fibroblasts, PMN, astrocytes Constitutively expressed in colon, small intestine, heart, lung, thymus, pancreas, spinal cord, ovary, placenta	Th2 response
NA	(CCL9/10)	Mouse only	Constitutively expressed in all mouse organs except brain; highest in lung, liver and thymus Induced in heart and lung	ND
17q11	CCL11	Eotaxin	Epithelial cells, EC, smooth muscle, cardiac muscle, Eo, dermal fibroblasts, mast cells, M Φ , Reed–Sternberg cells	Th2 response Eosinophil trafficking Mast cell trafficking Basophil trafficking, degranulation
NA	(CCL12)	Mouse only	Inducible in lung alveolar M Φ and smooth muscle cells; spinal cord. Constitutive expression in lymph node and thymic stromal cells	Allergic inflammation

NA, not applicable. Mo, monocyte; PMN, neutrophil; DC, dendritic cell; EC, endothelial cell; HEV, high endothelial venule; MPC, myeloid progenitor cell; plt, platelet; M Φ , macrophage; MCP, monocyte chemoattractant protein; MIP, macrophage inflammatory protein; RANTES, regulated upon activation normal T-cell expressed and secreted; MRP, MIP-related protein; HCC, hemofiltrate CC chemokine; TARC, thymus and activation related chemokine; PARC, pulmonary and activation related chemokine; ELC, Epstein–Barr virus-induced receptor ligand chemokine; LARC, liver and activation related chemokine; SLC, secondary lymphoid tissue chemokine; MDC, macrophage-derived chemokine; MPIF, myeloid progenitor inhibitory factor; TECK, thymus expressed chemokine; CTACK, cutaneous T cell-associated chemokine; MEC, mucosa-associated epithelial cell chemokine; ND, not determined.

Continued

chemokines are differentially and constitutively expressed in specific microenvironments of primary and secondary immune organs, and recruit hematopoietic precursor cells, dendritic cells (DC) and naïve and memory lymphocyte subsets via constitutively expressed receptors. Noxious stimuli induce inflammatory chemokines in diverse tissue cells and leukocytes. Inflammatory chemokine receptors are constitutively expressed on

myeloid and NK cells, but must be induced on activated effector lymphocytes. Dynamic shifts in receptor expression occur during DC and NK cell maturation and during lymphocyte maturation, activation and differentiation.^{6,7}

Inflammatory CXC and CC chemokine genes are found in two main clusters on human chromosomes 4q12-q21 and 17q11-q21, respectively.

Table 11.2 The human CC chemokine family—cont'd

Chromosomal location	Chemokine	Common aliases	Sources	Main immunologic roles
17q11-12	CCL13	MCP-4	Inducible in nasal and bronchial epithelial cells; dermal fibroblasts; PBMCs; atherosclerotic plaque EC and MΦ Constitutively expressed in small intestine, colon, thymus, heart and placenta	Th2 response
	CCL14a	HCC-1	Constitutively expressed in most organs; high plasma levels	ND
	CCL14b	HCC-3	Same as CCL14b except absent from skeletal muscle and pancreas	ND
	CCL15	HCC-2; Lkn-1	Inducible in Mo and DC Constitutive RNA expression in liver, gut, heart and skeletal muscle, adrenal gland and lung leukocytes.	ND
	CCL16	HCC-4; LEC	Constitutively expressed in liver, possibly many other organs. Also, Mo, T cells and NK cells express mRNA.	ND
16q13	CCL17	TARC	Constitutive in normal DC and Reed–Sternberg cells of Hodgkin's disease	Th2 response
17q11.2	CCL18	DC-CK1, PARC	Constitutive in Mo/MΦ, germinal center DC	DC attraction of naïve T cells
9p13.3	CCL19	ELC, MIP-3β	Constitutive on interdigitating DC in secondary lymphoid tissue	Naïve and memory T cell and DC homing to lymph node
2q36.3	CCL20	LARC MIP-3α	Constitutive in lymph nodes, peripheral blood leukocytes, thymus, and appendix Inducible in PBMC, HUVEC	DC homing to Peyer's patch Humoral response
9p13.3	CCL21	SLC, 6Ckine	Constitutive in lymphatic EC, HEV and interdigitating DC in T areas of 2° lymphoid tissue, thymic medullary epithelial cells and EC	Naïve and memory T cell and DC homing to lymph node
16q13	CCL22	MDC	Constitutive in DC and MΦ Inducible in Mo, T and B cells	Th2 response
17q12	CCL23	MPIF-1	Constitutive in pancreas and skeletal muscle	ND
7q11.23	CCL24	Eotaxin-2	Inducible in Mo	Eosinophil migration
19p13.3	CCL25	TECK	Constitutive in thymic stromal cells and small intestine	Thymocyte migration Homing of memory T cells to gut
7q11.23	CCL26	Eotaxin-3	Constitutive in heart and ovary Inducible on dermal fibroblasts and EC	Th2 response
9p13.3	CCL27	CTACK, Eskine	Constitutive in placenta, keratinocytes, testis and brain	Homing of memory and effector T cells to skin
5p12	CCL28	MEC	Constitutive in epithelial cells of gut, airway	Homing of T cells to mucosal surfaces

However, homeostatic chemokine genes are on multiple chromosomes in small clusters. Thirteen of the 19 human chemokine receptor genes are clustered at 3p21–23, and *CXCR1* and *CXCR2* are adjacent at 2q34–q35. Chemokine/receptor gene repertoire may vary among closely related species. Gene copy number and sequence may also vary among individuals of a species. Such variation may affect the risk of disease.

CHEMOKINE PRESENTATION MECHANISMS

Chemokines act locally. They are probably presented tethered to matrix or to endothelial cells via glycosaminoglycans or transmembrane domains. The tethering cell may have produced the chemokine, or else imported it by transcytosis from neighbors. The ligand-binding site includes the receptor N terminus and one or more extracellular loops, which allow

Table 11.3 Chemokine specificities for human 7TM chemokine receptors and chemokine-binding proteins. The standard name and most commonly used alias are listed for each chemokine

	CXCR2 CXCR1	CXCR3 (CD128) (CD183)	CXCR4 (CD184)	CXCR5	CXCR6	CXCR7	CCR1	CCR2	CCR3	CCR4 CCR5 (CD195)

Fig. 11.2 Chemokine signal transduction in chemotaxis. Depicted are key steps in two of the main pathways induced by most chemokines. The PI3K γ pathway is particularly important for cell migration. Chemokines are able to activate other pathways as well, including non-G_i-type G proteins, protein tyrosine kinases and MAP kinases. These pathways influence cell proliferation and activation. The model is modified from the Alliance for Cell Signaling (www.signaling-gateway.org). PLC, phospholipase C; PI3K, phosphatidylinositol-3-kinase; RGS, regulator of G protein signaling; DAG, diacylglycerol; IP₃, inositol trisphosphate; PIP, phosphatidylinositol phosphate; GAG, glycosaminoglycan; CK, chemokine; PKC, protein kinase C; GRK, G protein-coupled receptor kinase; GEF, guanine nucleotide exchange factor.

docking of the chemokine N-loop domain and 7TM domains, which accept the chemokine's N terminus and are critical for triggering. Tyrosine sulfation on the receptor N terminus facilitates ligand binding.

LEUKOCYTE RESPONSES TO CHEMOKINES

During inflammation, leukocytes undergo transendothelial migration, a multistep process. Chemokines regulate at least two of these steps.⁸ In an initial chemokine-independent step, leukocytes roll on inflamed endothelium in a selectin-dependent manner. Next, chemokines posted on endothelium stimulate rolling leukocytes to express activated β_2 integrins, which mediate firm adhesion via endothelial ICAMs. Leukocytes sense chemokine gradients, polarize, and become poised to crawl.⁹ Motion involves shear-dependent coordinated cytoskeletal remodeling, involving expansion of the leading edge (lamellipodium), myosin-based contraction at the trailing edge (uropod), release of the uropod from substrate, and membrane lipid movement. Navigation through tissue may require relays of chemokines and adhesion molecules.

Chemokines may also modulate cell proliferation and death pathways.¹⁰ Inflammatory chemokines may induce mediator release (e.g. defensins, proteases, perforins, histamine, eicosanoids), resulting in cytotoxic or vasomotor responses. Nevertheless, when injected systemically

chemokines are typically well tolerated. Some chemokines, e.g. CXCL9–11, have direct antibacterial activity.

CHEMOKINE SIGNALING PATHWAYS

Chemokines trigger chemokine receptors to act as guanine nucleotide exchange factors (GEF), mainly for G_i-type G proteins.^{11,12} This results in G protein activation and dissociation into α and $\beta\gamma$ subunits, which in turn leads to the activation of diverse G protein-dependent effectors, including phospholipases A₂, C (subtypes β_2 and β_3) and D, phosphatidylinositol-3-kinase γ (PI3K γ), protein tyrosine kinases (PTK) and phosphatases, low molecular weight GTPases, and mitogen-activated protein kinases (Fig. 11.2).

Cytosolic and calcium-independent PLA₂ catalyze the formation of arachidonic acid from membrane phospholipids and have been shown to enhance chemokine activation of human monocyte chemotaxis. PLC hydrolyzes PI-4,5-bisphosphate (PIP₂) to form 1,2-diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP₃). IP₃ induces Ca²⁺ release from intracellular stores which acts with DAG to activate protein kinase C (PKC). PI3K γ phosphorylates PIP₂ to form PIP₃, which recruits proteins

containing pleckstrin homology (PH) or PHOX (PX) domains to lamellipodium, thereby converting shallow extracellular chemokine gradients to steep intracellular effector gradients. Four PH domain-containing targets – AKT and GEFs for RAC, RHO and CDC42 – modulate distinct phases of cell movement in various model systems. RHO regulates cell adhesion and chemotaxis, and myosin contraction. RAC and CDC42 respectively control lamellipodia and filopodia formation. Downstream targets of RAC include PAK1, which also regulates myosin contraction.

G_i-INDEPENDENT EFFECTORS

Chemokines may activate effectors such as MAP kinases and nonreceptor PTKs by G_i-independent mechanisms. One proposed mechanism involves direct coupling to a scaffold/adaptor protein, such as β arrestin or a PDZ domain protein, which brings sequentially acting effectors into proximity of each other and the receptor. A second mechanism involves receptor cross-activation by inducing growth factor release. A third proposes JAK2 action upstream of G_i, e.g., for CCL2 chemotaxis of T cells. In a fourth, high concentrations of CCL5 form fibrillar aggregates that induce T-cell proliferation through a PTK-dependent mechanism.

REGULATION OF CHEMOKINE ACTION

Chemokine and chemokine receptor expression may be positively or negatively regulated at the transcriptional level by diverse factors, including proinflammatory cytokines, oxidant stress, viruses, bacterial products such as LPS and *N*-formyl peptides, cell adhesion, antigen uptake, T-cell co-stimulation, and diverse transcription factors including NF- κ B. Proinflammatory cytokines such as IL-1, TNF and IL-15 induce expression of many of the inflammatory chemokines involved in innate immunity, such as CXCL8. Immunoregulatory cytokines such as IFN- γ and IL-4 are more tightly focused on Th1 (CXCL9–11)- and Th2 (CCL11)-selective chemokines, respectively. Interferons, glucocorticoids and anti-inflammatory cytokines (e.g., IL-10, TGF- β) may inhibit inflammatory chemokine gene expression. Chemokines may also be regulated at the level of mRNA stability.

A chemokine gene may generate families of proteins that vary in activity and potency by alternative splicing and post-translational modification, especially N- and C-terminal proteolytic trimming. Identified proteases may target many chemokines (e.g., CD26 [dipeptidyl peptidase IV] and matrix metalloproteinases [MMP]), or few or only one (e.g., TACE [the TNF- α -converting enzyme], plasmin, urokinase plasminogen activator and cathepsin G).¹³ Chemokine action may be blocked by chemokine-binding proteins (e.g., Duffy), endogenous receptor antagonists, receptor decoys and autoantibodies. In addition, cytokines may convert a signaling receptor into a decoy (e.g., IL-10 inactivates CCR2 on monocytes). Also, a receptor may have different functions on different cell types. Chemokine receptor signaling can also be regulated by RGS (regulators of G protein signaling) proteins and by homologous and heterologous desensitization, which involves phosphorylation by G protein-coupled receptor kinases or PKC and PKA, respectively, and internalization by clathrin-dependent and -independent mechanisms.

CHEMOKINE REGULATION OF HEMATOPOIESIS

CXCL12 IN MYELOPOIESIS AND B LYMPHOPOIESIS

Most chemokines that modulate hematopoietic progenitor cell (HPC) proliferation *ex vivo* act early during hematopoiesis and are inhibitory.¹⁴ CXCL12 is an important exception.^{15,16} The most abundant chemokine in bone marrow, CXCL12 was originally identified as a pre-B-cell stimulatory factor from stromal cells that also enhanced HPC colony formation *ex vivo*. Later, mice lacking CXCL12 or its receptor CXCR4 were shown to have severe defects in bone marrow myelopoiesis and B-cell lymphopoiesis (Table 11.5). CXCR4 is also critical for mobilization of human peripheral blood progenitor cells from bone marrow in humans, and for engraftment of human hematopoietic stem cells in SCID mice.

CXCR4 is also expressed on platelets, megakaryocytes, and most mature peripheral blood leukocytes. However, its precise importance in trafficking is undefined, partly because CXCL12 and CXCR4 knockout mice die in the perinatal period. These animals have multiple developmental abnormalities, including a ventricular septal defect, defective gastric vascularization, and subtle defects in neurodevelopment. Thus CXCL12 and CXCR4 comprise an essential chemokine-receptor pair with unusually pleiotropic functions.

MYELOSUPPRESSIVE CHEMOKINES

When added to bone marrow culture systems *ex vivo*, many chemokines are able to suppress growth factor-dependent colony formation, apparently by acting directly on stem cells and early progenitors.¹⁵ The *in vivo* significance of *ex vivo* myelosuppressive activity remains unclear for most chemokines and chemokine receptors. CXCR2 is a notable exception, at least in mice. CXCR2^{-/-} mice develop massive neutrophilia, splenomegaly, myeloid hyperplasia, and expansion of HPCs. CXCR2-dependent myelosuppression may be important for opposing overstimulation of hematopoiesis induced by environmental flora, as this phenotype is absent in mice derived in germ-free conditions. These mice also develop lymph node B-cell hyperplasia, which may occur by an indirect mechanism.

T LYMPHOPOIESIS

During development T cells must migrate from the thymic cortex to the medulla. Chemokines and chemokine receptors are differentially expressed in the thymus and could coordinate migration. However, their precise roles remain unclear.

CCR9 and its ligand, CCL25, may be important, as competitive transplantation of CCR9^{-/-} bone marrow is less efficient than normal marrow at repopulating the thymus of lethally irradiated Rag-1^{-/-} mice. CCL25 is expressed by medullary dendritic cells and both cortical and medullary epithelial cells. CCR9 is expressed on the majority of immature CD4⁺CD8⁺ thymocytes, but is downregulated during transition to the CD4⁺ or CD8⁺ single-positive stage (Fig. 11.3). Just before thymic egress, thymocytes become CCR9 negative and upregulate L-selectin. Transition from CD4⁺CD8⁺ thymocytes in the cortex to CD4 or CD8

Table 11.5 Some phenotypes of chemokine receptor knockout mice

Receptor	Phenotype		
	Infectious disease	Inflammation	Development
CXCR2	Increased susceptibility to: <i>T. gondii</i> Brain abscess <i>Onchocerca volvulus</i> <i>E.coli</i> pyelonephritis	Reduced: Wound healing <i>A. fumigatus</i> AHR urate crystal-induced synovitis	Expansion of neutrophils and B cells in blood, marrow and lymphoid organs (not seen when derived in germ-free environment)
CXCR3	Increased susceptibility to MTb	Delayed cardiac allograft rejection	
CXCR4			Perinatal lethality Defective: Ventricular septum bone marrow myelopoiesis B-cell lymphopoiesis Gastric vascularization Cerebellar granule cell migration
CXCR5			Few Peyer's patches, no inguinal LN Defective germinal centers and B cell homing to LN
CXCR7			Defective cardiac development
CCR1	Increased susceptibility to: <i>T. gondii</i> Pneumonia virus of mice <i>A. fumigatus</i>	Increased: Th1 response and glomerular injury in nephrotoxic nephritis model Th2 response to SEA Reduced: Neutrophilic alveolitis in pancreatitis-ARDS model airway remodeling and Th2 response in <i>A. fumigatus</i> model Th1 response and resistance to EAE Th1 response to PPD Delayed cardiac allograft rejection	NR
CCR2	Increased susceptibility to: <i>C. neoformans</i> Mouse hepatitis virus <i>L. monocytogenes</i> <i>L. major</i> <i>M tuberculosis</i> Resistance to: <i>L. donovani</i> Influenza A	Decreased: EAE response to PPD Atherosclerosis Cardiac allograft rejection AHR to CRA Dextran sulfate-mediated colitis Thioglycollate-induced peritonitis FITC and bleomycin-induced pulmonary fibrosis recruited to injured nerve DTH monocyte extravasation Increased: AHR to OVA AHR to <i>A. fumigatus</i> glomerulonephritis in antglomerular basement membrane antibody model	Enhanced myeloid progenitor cell cycling and apoptosis

SEA, *Schistosoma mansoni* soluble egg antigen; OVA, ovalbumin; CRA, cockroach antigen; AHR, airway hyperreactivity; LN, lymph node; DC, dendritic cell; DTH, delayed type hypersensitivity; NR, not reported.

Continued

Table 11.5 Some phenotypes of chemokine receptor knockout mice—cont'd

Receptor	Phenotype		
	Infectious disease	Inflammation	Development
CCR3		ip OVA sensitization→OVA challenge: Increased AHR and airway mast cells; decreased airway eos, trapped between elastic lamina and endothelial cells Epicutaneous OVA sensitization→OVA challenge: Protection from allergic skin inflammation and AHR. Eos and mast cells not recruited to skin or lung	Decreased eos in gut
CCR4		Increased susceptibility to Ips	
CCR5	Increased susceptibility to: <i>L. monocytogenes</i> <i>C. neoformans</i> <i>T. gondii</i> Influenza A <i>L. major</i> Resistance to: <i>L. donovani</i>	Decreased: Dextran sulfate-mediated colitis Lps toxicity Mouse hepatitis virus-induced demyelination due to decreased Mφ recruitment to CNS Cardiac allograft rejection Increased: DTH Humoral response to T dependent Ag	
CCR6		Defective CRA-induced allergic airway inflammation Increased contact hypersensitivity to 2,4- dinitrofluorobenzene Resistance to DTH to allogeneic splenocytes	Absent myeloid CD11b+ CD11c+ dendritic-cells in subepithelial dome of Peyer's patches. Increased T cells in intestinal mucosa Impaired humoral immune response to orally administered antigen and to rotavirus.
CCR7		Delayed humoral response Defective contact sensitivity Defective DTH	Defective lymphocyte and DC migration to LN Undeveloped T-cell zones Impaired trafficking of T cells and DC to LN
CCR8		Defective SEA-induced granuloma formation; Decreased OVA- and CRA-induced allergic airway inflammation	
CCR9			Decreased preproB cells, but nl T and B cells Decreased ratio of gut intraepithelial T-cell-to-epithelial cell ratio due to decreased γδ T cells
CX3CR1	Increased susceptibility to <i>Salmonella</i> infection	Resistance to cardiac allograft rejection in cyclosporine A treated animals Resistance to atherosclerosis	
Duffy		Increased or decreased neutrophil mobilization, depending on the model	
D6		Psoriasiform dermatitis	

Fig. 11.3 Chemokine receptor control of leukocyte trafficking. Shown are routes among primary and secondary immune organs and the periphery, leukocyte subtypes trafficking on those routes, and some of the chemokine receptors that appear to be most important in regulating each route. Tn, naïve T cells; Tp, precursor T cells; Tm, memory T cells; Tcm, central memory T cells; T_{fh}, follicular help T cells; iDC, immature dendritic cells; N, neutrophil; Eo, eosinophil; MΦ, macrophage; Mo, monocyte; NK, natural killer cell; HSC, hematopoietic stem cell; GC, germinal center; dp, double positive; sp, single positive. The model is based primarily on studies of mice where the relevant gene has been inactivated by gene targeting.

single-positive thymocytes in the medulla is associated with upregulation of CCR4 and CCR7, receptors for CCL22, and CCL19 and CCL21, respectively, which are expressed in the medullary stroma. Accordingly, these chemokines attract thymocytes between the late cortical and medullary stages of development *in vitro*. Neutralization studies suggest that egress of newly formed T cells from the fetal thymus to the circulation is mediated by CCL19, which is selectively localized on endothelial cells of medullary venules and acts at CCR7 on mature thymocytes.

PHAGOCYTE POSITIONING IN PERIPHERAL TISSUE

Factors controlling specific positioning of myeloid cells in peripheral tissues include CXCL14 for macrophages in lung, and CCL11 and its receptor CCR3 for eosinophils in spleen and the gastrointestinal tract.¹⁷ CCR6 regulates positioning of immature myeloid CD11c⁺CD11b⁺ DC in the subepithelial dome of Peyer's patches. This may partly explain why humoral immune responses within the gut mucosa are abnormal in CCR6^{-/-} mice. However, CCR6 expression on B cells and subsets of T cells may also be responsible. CX3CR1 also regulates the location of

myeloid DC in Peyer's patch and may be important for antigen sampling from the intestine.

CHEMOKINE REGULATION OF THE IMMUNE RESPONSE

The two major immune subsystems, innate and adaptive, are deployed separately but assembled in part by specific sets of chemokines and dynamic changes in chemokine receptor expression on subsets of B and T lymphocytes and DC (Fig. 11.3).

INNATE IMMUNITY

Platelet-derived chemokines

Made primarily during platelet development, stored in platelet α granules, and rapidly released during platelet degranulation, ELR⁺ CXCL4 and CXCL7 may be among the first chemokines to appear at sites of tissue injury and infection, particularly when there is hemorrhage and

vascular damage, and may reach high concentrations.¹⁸ CXCL4 aggregates to form tetramers critical for binding to chondroitin sulfate proteoglycans, their major known binding sites. In contrast, CXCL7 is activated by sequential proteolysis of its N terminus. The prepropeptide form, named platelet basic protein (92 aa), is trimmed during platelet maturation to produce the 85 aa major stored form, named connective tissue activating peptide-III (CTAP-III), which is inactive on neutrophils. CTAP-III is further processed during degranulation to 81 aa β -thromboglobulin, also inactive. This is then cleaved by a cell surface-bound cathepsin G-like enzyme on neutrophils to form 70 aa CXCL7, which has high homology to CXCL4 (70% aa identity). Thus CXCL7 may function as an immediate-early mediator of neutrophil recruitment released from platelets at sites of inflammation. Although it is not a prominent leukocyte chemoattractant and does not induce degranulation of neutrophil lysosomal enzymes, CXCL4 is able to induce secondary granule exocytosis and release matrix-degrading enzymes that may facilitate neutrophil penetration of infected or injured tissues.

The importance of CXCL8 and CXCR2

All seven ELR⁺ CXC chemokines preferentially recruit neutrophils *in vitro* by binding to CXCR2. One of these, CXCL8, is also a potent agonist at CXCR1, which is co-expressed at similar levels on neutrophils.¹⁹ These seven chemokines are rapidly inducible, but may differ biologically owing to temporal and spatial differences in expression. This may provide a mechanism for graded navigation of neutrophils through tissue. Blocking studies in multiple animal models have demonstrated the importance of CXCL8 and CXCR2 in neutrophil accumulation in response to infectious and noninfectious stimuli. The role of CXCR1 is still unclear. Intradermal injection of CXCL8 in humans causes rapid (<30 min) and selective accumulation of large numbers of neutrophils in perivascular regions of the skin without causing edema. Moreover, tissue-specific transgenic overexpression of mouse CXCL8 paralogs KC and MIP-2 has suggested that *in vivo* these factors may recruit cells but not independently activate cytotoxic mechanisms. In a human blister model, endogenous CXCL8 peaks at ~24 hours, whereas C5a and leukotriene B₄, which also recruit neutrophils, appear earlier. Thus the primary role of CXCL8 may be to amplify early inflammatory responses. CXCL1, 2, 3, 7 and 8 have also been reported to induce basophil chemotaxis and histamine release *in vitro*, which together with other factors such as complement-derived anaphylatoxins may promote vasodilatation during early stages of the innate immune response. CC chemokines can also activate human neutrophils, but this typically requires pre-stimulation of the cells with IFN- γ and other factors able to induce expression of appropriate receptors.

Monocyte recruitment typically follows neutrophil accumulation with delayed kinetics and may be mediated by multiple inflammatory CC receptors and CX3CR1. CCR2 and CX3CR1 are particularly important and define two monocyte subsets, CX3CR1⁺CCR2⁻ and CCR2⁺CX3CR1⁻, with distinct trafficking properties in mice.

NK cells

Human NK cell subsets express unique repertoires of chemokine receptors.²⁰ The CD56^{dim}CD16⁺ subset, which is associated with high cytotoxic capacity and low cytokine production, expresses primarily

CXCR1 and CX3CR1. The minor subset of CD56^{bright}CD16^{dim} cells, which produce large amounts of cytokines but have low killing capacity, preferentially express CCR7. The exact profile of chemokine receptor expression can be modulated by adherence and stimulation *ex vivo* with IL-2. Cognate chemokines chemoattract NK cells and promote degranulation and killing. The importance of chemokines in NK cell function *in vivo* is well illustrated by mouse cytomegalovirus (MCMV) infection, a cause of hepatitis. MCMV induces CCL3 production in the liver, which is required for recruitment of NK cells. NK cells are the major source of IFN- γ in this model, and IFN- γ induces CXCL9, which is required for protection. Thus a cytokine–chemokine–cytokine cascade is required for NK cell-mediated host defense against this pathogen.

Dendritic cells and transition to the adaptive immune response

Transition from the innate to the adaptive phases of the immune response involves antigen uptake by antigen-presenting cells, especially dendritic cells, mediated by Fc and complement phagocytic receptors, as well as pattern recognition receptors (PRRs), including DC-SIGN and Toll-like receptors (TLRs) (Chapter 3). Both TLR2 and TLR4 signaling induces expression of CCL3, CCL4 and CCL5. However, TLR2 selectively induces CXCL8, whereas TLR4 selectively induces CXCL10. CXCL8 may increase neutrophil migration to the site, whereas CXCL10 may enhance NK cell or Th1 effector T-cell homing.²¹ Pathogens may skew the nature and magnitude of the immune response in a specific direction by means of specific PRR ligands.

The chemokine receptors expressed on DCs may vary according to the nature of the inflammatory stimulus and type. For example, blood-derived plasmacytoid and myeloid DCs express a similar repertoire of inflammatory chemoattractant receptors, but they are functional only on myeloid DCs. CCL3, CCL4 and CCL5 may be particularly important for recruiting additional mononuclear phagocytes and DCs to sites of infection. This can amplify the late stage of the innate immune response. In the extreme, this may evolve into endotoxic shock. Consistent with this idea, genetic disruption of the CCL3/CCL4/CCL5 receptor CCR5 renders mice relatively resistant to LPS-induced endotoxemia. CCR4^{-/-} mice are also resistant to lethality induced by intraperitoneal administration of LPS. This is associated with reduced macrophage extravasation to the peritoneum and production of the CCR4 ligand CCL17, which can be produced by DCs.

ADAPTIVE IMMUNITY

Afferent trafficking to secondary lymphoid tissue

The homeostatic receptors CXCR5 and CCR7 and their ligands are major regulators of the immune response, acting at the level of B- and T-lymphocyte and DC trafficking to and within secondary lymphoid tissue.²² DC maturation in peripheral tissues is associated with down-regulation of inflammatory receptors, which may be important for recruitment, migration and retention in the periphery, and reciprocal upregulation of CCR7, which mediates mature DC migration to draining lymph nodes. Inflammatory receptors may also contribute to afferent trafficking, as demonstrated for CCR2 on Langerhans' cells in a mouse

model of *Leishmania* infection. CCR7 is also a major lymph node trafficking receptor for naïve T cells.

The CCR7 ligand CCL21 is constitutively expressed on afferent lymphatic endothelium, high endothelial venules (HEV), stromal cells and interdigitating dendritic cells in T zones of lymph nodes, Peyer's patches, mucosa-associated lymphoid tissue and spleen. It is not expressed in B-cell zones or sinuses. CCL19, another CCR7 ligand, is also restricted to the T zone and is expressed on interdigitating DCs.

CCR7^{-/-} mice and the *plt* mouse, which is naturally deficient in CCL19 and a CCL21 isoform expressed in secondary lymphoid organs, have similar phenotypes: atrophic T-cell zones populated by a paucity of naïve T cells. This and the failure of activated DC to migrate to lymph node from the skin of these mice explain why contact sensitivity, delayed-type hypersensitivity and antibody production are severely impaired.

CXCR5 is expressed on all peripheral blood and tonsillar B cells, but on only a fraction of bone marrow B cells. Its ligand CXCL13 is expressed constitutively on follicular high endothelial venules (HEV) and controls trafficking of CXCR5 positive B and T cells from the blood into follicles. In CXCR5^{-/-} mice B cells do not migrate to lymph node, Peyer's patches are abnormal, and inguinal lymph nodes are absent. CXCL13 is also required for B1 cell homing, natural antibody production, and body cavity immunity. CXCR5^{-/-} mice still can produce antibody, perhaps partly because B cells and follicular DC are able, by an unknown mechanism, to form ectopic germinal centers within T zones of the periarteriolar lymphocyte sheath of the spleen.

CXCR5 and CCR7 are probably not the only chemokine receptors responsible for afferent trafficking of leukocytes to lymph nodes. CCL9 has been reported to mediate monocyte homing. CCR4 and CCR8 are expressed on a subset of human peripheral blood CD4⁺CD25⁺CTLA4⁺ T cells, which are associated with suppression of T-cell responses and may be important in the generation of tolerance.²³ Mature DCs attract these cells *in vitro* by secreting CCR4 ligands CCL17 and CCL22. In addition, inflamed peripheral tissues may exert 'remote control' over which leukocyte populations home to draining lymph nodes from the blood by 'projecting' their local chemokine profile to HEVs of the draining lymph node. Migration of T cells to splenic red pulp may involve local production of CXCL16. NK-T cells, activated CD4 T cells and activated CD8 T cells are found in this area. They express the CXCL16 receptor CXCR6. CXCL16 is also made by DCs in the T zone, and CXCR6 is also found on intraepithelial lymphocytes. Thus, CXCL16 may function in T-cell-DC interactions and in regulating movements of activated T cells in the splenic red pulp and in peripheral tissues.

Migration within lymph node microenvironments

CXCR5 is expressed on a majority of memory CD4 T cells in the follicles of inflamed tonsils. Follicular helper T cells (T_{FH}), a CD57⁺ subset of CXCR5⁺ T cells, lack CCR7, which licenses them to move from the T zone following activation to the follicles, where they provide help for B-cell maturation and antibody production. They do not produce Th1 or Th2 cytokines upon activation. Reciprocally, B cells activated by antigen in the follicles upregulate CCR7 and move towards the T zone. Thus B-T interaction may be facilitated by reciprocal movement of these cells, which may be influenced by the balance of chemokines made in adjacent lymphoid zones.²⁴ CXCR4 signaling may also be important in naïve and memory B-cell trafficking to germinal centers, and CCR5

ligands may guide naïve CD8 T cells to sites of CD4 T cell-dendritic cell interaction in lymph nodes.²⁵

Efferent trafficking

Naïve lymphocytes that do not encounter antigen continue to recirculate between the blood and secondary lymphoid tissue without acquiring any tissue-specific homing properties. Most antigen-stimulated T cells die by apoptosis. The survivors may be divided into functionally distinct subsets marked by characteristic patterns of chemokine receptor expression. In general, the trafficking properties of these cells are not well understood. Within CD4 T cells, three memory subsets and two main effector subsets have been proposed. The memory subsets include T_{FH} cells, described previously, effector memory (T_{EM}) and central memory cells (T_{CM}). T_{EM} express L-selectin but lack CCR7. They may traffic through peripheral tissues as immune surveillance cells, rapidly releasing cytokines in response to activation by recall antigens. T_{CM} express CCR7 and lymph node homing receptors. They traffic between the blood and secondary lymphoid organs, but are not polarized and lack immediate effector function. Instead, they may interact efficiently with DCs in lymph nodes and differentiate into T_{EM} upon secondary stimulation. Highly heterogeneous, multifunctional human T_{EM} may be produced early in differentiation and may become stable resting cells.²⁶ Both memory populations can be activated by APCs and antigen.

The classic effector subsets Th1 and Th2 (Chapters 17 and 18) down-regulate CXCR5 and CCR7 and upregulate inflammatory chemokine receptors. This switch facilitates their exit from lymph nodes via efferent lymphatics and their homing to inflamed sites. *In vivo*, combinations of receptors rather than any single receptor appear to hold the strongest association with these functional subsets in the blood, and there is a hierarchy of chemokine receptor expression associated with the age of the cell.²⁶

In vivo, Th1 cells, which by the simplest definition secrete IFN- γ but not IL-4 and control cellular and humoral immunity to intracellular pathogens, more frequently express CXCR3, CXCR6, CCR2, CCR5 and CX3CR1 than do Th2 cells. In contrast, Th2 cells, which express IL-4 but not IFN- γ and are associated with cellular and humoral immunity to extracellular pathogens and allergic inflammation, more frequently express CCR3, CCR4 and CCR8 than do Th1 cells. CXCR3 expression has been most consistently associated with Th1 immune responses and Th1-associated disease. Consistent with this, its agonists CXCL9-11 are highly induced by IFN- γ but not IL-4. Thus in Th1 immunity there is the potential for a positive feedback loop in which IFN- γ induces production of CXCL9-11, which then recruit CXCR3⁺ Th1 cells that produce IFN- γ . 'Th1 chemokines' may also help maintain Th1 dominance through their ability to block CCR3. Specific cytokines, microenvironments and inflammatory stresses may differentially regulate CXCL9-11 expression, which may account for specialized biological roles.

Similarly, in Th2 immunity IL-4 and IL-13 made at inflamed sites in the periphery may induce production of CCL7, CCL11 and other CCR3 ligands, the CCR4 ligands CCL17 and CCL22, and the CCR8 ligand CCL1. CCR3 is expressed on a subset of Th2 T lymphocytes as well as on eosinophils and basophils, the three major cell types associated with Th2 type allergic inflammation. Th2 cells are also associated with CCR4 expression. Arrival of Th2 cells amplifies a positive feedback loop through the secretion of additional IL-4. CCL7 and CCL11 may block Th1 responses by antagonizing CCR2, CXCR3 and CCR5.

Th17 cells, a recently described effector CD4 T cell subset that makes IL-17, all express CCR6.

CD4 T-cell differentiation

Some chemokines appear to also regulate the differentiation of Th1 and Th2 cells. CCL2 and its receptor CCR2 have been most extensively studied in this regard. At first glance their contribution appears contradictory, as *in vivo* CCR2 is strongly associated with Th1 immune responses and CCL2 is associated with Th2 responses. However, CCL2 appears to promote Th2 polarization directly, by inhibiting IL-12 production in monocytes and by enhancing IL-4 but not IFN- γ production in memory and activated T cells. Thus, CCL2 influences both innate immunity, through effects on monocyte trafficking, and adaptive immunity, through control of Th-cell polarization and trafficking.²⁷ In the case of aerosol challenge with *Mycobacterium tuberculosis* in CCR2^{-/-} mice, DC migration to draining lymph nodes is markedly impaired, which preempts any direct effects of CCL2 on T cells. Why CCL2 and CCR2 have opposite effects on Th polarization is unclear, but is most likely due to ligand-receptor promiscuity.

The role of CCL3 and its receptors on T-cell polarization is also complex. In mice, CCL3 can directly enhance IFN- γ production in activated T cells, and CCL3 neutralization attenuates Th1-driven experimental autoimmune encephalomyelitis and Th1-dependent granuloma formation. Nevertheless, mice lacking the CCL3 receptor CCR1 typically have reduced Th2 responses. This suggests a role for CCR5 in mediating the Th1-polarizing effects of CCL3. This is consistent with the role of CCR5 in mediating CD8 α^+ DC trafficking and IL-12 production in the spleen in mice injected with Stag, a soluble *Toxoplasma gondii* antigen preparation. Nevertheless, CCR5^{-/-} mice have also been reported to have enhanced delayed-type hypersensitivity reactions and increased humoral responses to T cell—dependent antigenic challenge. This indicates a role for CCR5 in downmodulating certain T cell—dependent immune responses as well.

Tissue-specific lymphocyte homing

CLA⁺ T lymphocytes, which home to skin, preferentially express CCR4 and CCR10.²⁸ The CCR4 ligand CCL22 is made by resident dermal macrophages and DCs, whereas the CCR10 ligand CCL27 is made by keratinocytes. Blocking both of these pathways, but not either one alone, has been reported to inhibit lymphocyte recruitment to the skin in a DTH model. This implies that these two molecules may act redundantly as well as independently of inflammatory chemokines.

Homing to the small intestine is determined in part by T-lymphocyte expression of the integrin $\alpha_4\beta_7$ and CCR9.²⁸ The $\alpha_4\beta_7$ ligand MAdCAM-1 and the CCR9 ligand CCL25 co-localize on normal and inflamed small intestinal endothelium. Most T cells in the intraepithelial and lamina propria zones of the small intestine express CCR9. These cells, which are mainly TCR $\gamma\delta^+$ or TCR $\alpha\beta^+$ CD8 $\alpha\beta^+$, are reduced in the small intestine of CCR9^{-/-} mice.

As B cells differentiate into plasma cells, they downregulate CXCR5 and CCR7 and exit lymph nodes. B immunoblasts expressing IgG coordinately upregulate CXCR4, which promotes homing to the bone marrow, whereas B immunoblasts expressing IgA specifically migrate

CLINICAL RELEVANCE

Examples of the chemokine system and disease

- >> WHIM syndrome (warts, hypogammaglobulinemia, infection, myelokathexis) and truncating gain-of-function mutations in CXCR4.
- >> Resistance to *Plasmodium vivax* malaria and with a nonfunctional promoter variant in Duffy.
- >> Resistance to initial HIV infection and susceptibility to West Nile virus disease in patients homozygous for a loss-of-function CCR5 allele (CCR5 Δ 32).
- >> Reduction of HIV viral load in AIDS patients treated with CCR5 antagonists.
- >> Induction of Kaposi's sarcoma-like tumors in mice forced to express human herpes virus 8 vGPCR.
- >> Atherosclerotic cardiovascular disease and CX3CR1. Reduced risk is associated with loss-of-function CX3CR1 M280 allele.
- >> Autoimmune heparin-induced thrombocytopenia and CXCL4. Caused by autoAb production to CXCL4-heparin complexes, causing activation of platelets and microvascular endothelial cells.
- >> Chronic renal allograft rejection and CCR5. Reduced risk associated with homozygous CCR5 Δ 32.
- >> Rheumatoid arthritis and CCR5. Reduced risk associated with CCR5 Δ 32.
- >> Eosinophilic esophagitis and CCL26. Disease is associated with CCL26 variant.

to mucosal sites. Like gut-homing T cells, B immunoblasts that home to small intestine express $\alpha_4\beta_7$ integrin and CCR9 and respond to CCL25.²⁹

CHEMOKINES AND DISEASE

There is a vast literature correlating the presence of chemokines with diverse human diseases, but strong evidence that they are actually involved in pathogenesis is available for only a small subset of these.

Opposite effects of CCR5 in HIV and West Nile virus infection

HIV envelope glycoprotein gp120 mediates fusion of the viral envelope with the target cell membrane by binding to CD4 and a chemokine receptor.³⁰ Both CCR5 and CXCR4 physically associate with CD4 and gp120, and are therefore referred to as 'HIV co-receptors'. HIV strains are functionally classified and named according to their specificity for CXCR4 (X4 strains), CCR5 (R5 strains), or both (R5X4 strains).

Fig. 11.4 CCR5 facilitates HIV infection, but restricts West Nile virus infection. The mutant receptor CCR5Δ32 is not expressed on the cell surface and cannot be used for cell entry by HIV or to respond to West Nile virus.

The importance of CCR5 in clinical HIV/AIDS is revealed most clearly by *CCR5Δ32*, a nonfunctional allele that occurs in ~20% of North American Caucasians. Homozygotes are highly resistant to R5 HIV, the main transmitting strain, and HIV-infected heterozygotes have slower disease progression. Homozygotes appear healthy, as do unstressed CCR5 knockout mice. This has encouraged the development of CCR5-blocking agents for application in HIV/AIDS. Recently, maraviroc (Pfizer) has been approved by the FDA for this indication.

CCR5 is also important in the pathogenesis of West Nile virus (WNV) infection, but in this case it plays a protective role (Fig. 11.4).³¹ In mice, WNV challenge is uniformly fatal when CCR5 has been genetically disrupted, and in humans homozygous *CCR5Δ32* is strongly associated with symptomatic WNV infection in patient cohorts. The mechanism appears to be a decrease in antiviral defense by diminishing recruitment of CCR5⁺ leukocytes into the brain. Thus the same receptor that appears to promote HIV infection restricts WNV infection. Theoretically, therefore, CCR5-blocking agents could increase the risk of viral infections other than HIV, particularly in the setting of HIV/AIDS, where the immune system is already compromised.

Malaria

Analogous to CCR5 and HIV, Duffy, the 7TM promiscuous chemokine-binding protein, is required for infection of erythrocytes by *Plasmodium vivax*, a major cause of malaria.³² The parasite ligand, which is named the *Plasmodium vivax* Duffy binding protein (PvDBP), is expressed in micronemes of merozoites and binds to the N-terminal domain of Duffy via a cysteine-rich domain. This interaction is required for junction formation during invasion, but not for initial binding or parasite orientation. A deficiency of Duffy expression has been described in individuals who have inherited a single nucleotide substitution in the Duffy promoter (−46C) at an erythroid-specific GATA-1 site. This deficiency is fixed in sub-Saharan Africa, but not in other malaria-endemic regions of the world. Accordingly, *P. vivax* malaria is rare in

sub-Saharan Africa, but common in Central and South America, India and Southeast Asia. Fixation of the mutation in Africa presumably occurred because of positive selective pressure from malaria. Identification of the −46C mutation in the Melanesian Duffy allele among individuals living in a *P. vivax*-endemic region of Papua New Guinea provides an opportunity to test this hypothesis prospectively. Together with *CCR5Δ32*, Duffy −46C is the strongest genetic resistance factor known for any infectious disease in man. Duffy deficiency in man and knockout mice is not associated with any known health problems.

WHIM Syndrome

Truncating mutations in the C tail of CXCR4 that prolong receptor signaling by delaying desensitization and blocking internalization have been strongly linked genetically to family cohorts with WHIM syndrome (warts, hypogammaglobulinemia, infection and myelokathexis [neutropenia without maturation arrest]).³³ Myelokathexis can be explained by exaggeration of the normal bone marrow retention action of CXCR4 for myeloid cells. The exact mechanism underlying the selective predisposition to papillomavirus infection is unknown.

Atherosclerosis

Macrophages are the dominant leukocyte in atherosclerotic lesions and are associated with the presence of macrophage-targeted chemokines such as CCL2, CCL5 and CX3CL1. *CCL2^{−/−}*, *CCR2^{−/−}*, *CX3CL1^{−/−}*, and *CX3CR1^{−/−}* mice demonstrate a reduction in the accumulation of macrophages which is associated with a reduction in vessel wall lesion size. Adoptive transfer studies with bone marrow from *CXCR2^{−/−}* mice have also revealed a role for that receptor in promoting atherosclerosis in mouse models, apparently by promoting monocyte adhesion to early atherosclerotic endothelium through interaction with its mouse ligand KC and activation of the VLA-4/VCAM-1 adhesion system.

KEY CONCEPTS

The viral chemokine system

Studies of the viral chemokine system can yield insight into the role of chemokines in immunoregulation. Viral chemokine elements may also have applications as therapeutic agents.

>> Structural classification

Chemokines (e.g., HHV8 vMIP-I, II and III)
7TM chemokine receptors (e.g., HCMV US28, HHV8 vGPCR)
Chemokine-binding proteins (e.g., γ HV68 vCKBP-III)
Chemokine mimics (e.g., HIV gp120)

>> Functional classification

Cell entry factors (e.g., HIV gp120)
Leukocyte chemoattractants (e.g., HHV8 vMIP-II)
Immune evasion
Chemokine scavengers (e.g., γ HV68 vCKBP-III)
Chemokine receptor antagonists (e.g., MCV MC148-R)
Angiogenic factors (e.g., HHV8 vGPCR)
Growth factors (e.g., HHV8 vGPCR)

The CX3CR1 genetic variant CX3CR1-M280, which lacks normal CX3CL1-dependent adhesive function under conditions of physiologic flow, has been associated with a reduced risk of atherosclerotic vascular disease in human.³⁴ Mechanistic studies suggest that CX3CL1 on coronary artery smooth muscle cells anchors macrophages via CX3CR1.

Kaposi's sarcoma

HHV8 provides an example of the function of virally encoded chemokines and chemokine receptors. It encodes three CC chemokines, vMIP-I, II and III, as well as a constitutively active CC/CXC chemokine receptor named vGPCR, which is encoded by ORF74. All of these factors are angiogenic and may contribute to the pathogenesis of Kaposi's sarcoma (KS), a highly vascular multicentric nonclonal tumor caused by HHV8, typically in the setting of immunosuppression such as in HIV/AIDS. Consistent with this, vGPCR induces KS-like tumors when expressed in transgenic mice.³⁵ The mechanism may involve activation of NF- κ B and the induction of angiogenic factors and proinflammatory cytokines. This virus appears to have converted a hijacked receptor, probably CXCR2, into a regulator of gene expression.

Autoimmunity

Two human diseases have been identified in which chemokines act as autoantigens for autoantibodies. The first, heparin-induced thrombocytopenia (HIT), is the only human autoimmune disease directly linked mechanistically to chemokines. An established risk factor for thromboembolic complications of heparin therapy, HIT occurs in 1–5% of patients treated with heparin, and is the result of autoantibodies that bind specifically to CXCL4–heparin complexes in plasma. The second, autoimmune myositis, is associated with autoantibodies to histidyl tRNA synthetase, a protein synthesis factor that is also able to induce DC chemotaxis, apparently by acting as an agonist at CCR5. Its exact importance in promoting inflammation in myositis has not been established.

In general, T cell-dependent autoimmune diseases in human, such as psoriasis, multiple sclerosis (MS), rheumatoid arthritis (RA), and type I diabetes mellitus, are associated with inflammatory chemokines and tissue infiltration by T lymphocytes and monocytes expressing inflammatory chemokine receptors. The relative importance of these is not yet known. Patients homozygous for the CCR5 null allele *CCR5 Δ 32* have been reported who have MS, indicating that this receptor is not required for disease. An association of this allele with outcome in MS has not been firmly established. CCL2 and CCR2, and to a lesser extent CCL3 and CCR1, knockout mice have reduced disease in experimental allergic encephalomyelitis (EAE), a model of MS. Moreover, neutralization of CCL3 and CCL2 respectively markedly reduced the early and relapsing phases of EAE.

MCP-1, a dominant negative antagonist of CCL2, inhibits arthritis in the MRL-*lpr* mouse model of RA, suggesting a potential role for CCL2 and CCR2. Met-RANTES, a chemically modified variant of CCL5 that blocks CCR1, CCR3 and CCR5, was beneficial in a collagen-induced arthritis model in DBA/I mice. A meta-analysis has shown a protective effect for *CCR5 Δ 32* in RA. In the NOD mouse model of diabetes, insulinitis and hyperglycemia were reduced in CCL3 knockout mice.

Paradoxically, in some cases blocking chemokine receptors may lead to increased inflammation, as shown for CCR1 and CCR2 in nephrotoxic nephritis and glomerulonephritis mouse models. This is associated with increased renal recruitment of CD4 and CD8 T cells, macrophages, and enhanced Th1 immune responses. The exact mechanism remains unclear.

Acute neutrophil-mediated inflammatory disorders

Many neutrophil-mediated human diseases have been associated with the presence of CXCL8, including psoriasis, gout, acute glomerulonephritis, acute respiratory disease syndrome (ARDS), rheumatoid arthritis and ischemia–reperfusion injury. Systemic administration of neutralizing anti-CXCL8 antibodies is protective in diverse models of neutrophil-mediated acute inflammation in the rabbit (skin, airway, pleura, glomeruli), providing proof of concept that CXCL8 is a nonredundant mediator of innate immunity and acute pathologic inflammation in these settings. CXCR2 knockout mice are less susceptible to acute urate crystal-induced gouty synovitis. And, SB-265610, a nonpeptide small molecule antagonist with exquisite selectivity for CXCR2, prevents neutrophil accumulation in the lungs of hyperoxia-exposed newborn rats. Together these results identify CXCL8 and its receptors as candidate drug targets for diseases mediated by acute neutrophilic inflammation. CXCR2 knockout mice also have delayed wound healing.

Transplant rejection

An advantage of transplant rejection over other animal models of human disease is that in both humans and animals the time of antigenic challenge is precisely known. The most extensive analysis of the role of chemokines in transplant rejection has been carried out in an MHC class I/II-mismatched cardiac allograft rejection model in the mouse, which is mediated by a Th1 immune response.³⁶ Similar sets of inflammatory chemokines are found in the mouse model as in the human disease. ELR CXC chemokines and CCL2 appear early, and are probably made by engrafted blood vessel endothelial cells. These are associated with neutrophil and mononuclear cell accumulation. On day 3 after engraftment CCL2 is still present and the three CXCR3 ligands CXCL9–11 and the CCR5 ligands

CCL4 and CCL5 appear. Of the CXCR3 ligands, CXCL10 appears earliest and in the largest amounts, probably in response to IFN- γ coming from NK cells. This phase is associated with transition to an adaptive immune response, with accumulation of trafficking of recipient T cells, macrophages and DCs to the graft, followed by acute and chronic rejection. Graft arteriosclerosis, which is distinct from the lipid-driven disease, may be driven in part by CXCL10 and IFN- γ .

Analysis of knockout mice has demonstrated that although multiple chemokine receptors contribute to rejection in this model, there is a marked rank order: CXCR3 > CCR5 > CCR1 = CX3CR1 = CCR2. Most impressively, rejection and graft arteriosclerosis do not occur if the recipient mouse, treated with a brief, subtherapeutic course of cyclosporine A, is CXCR3^{-/-}, or if the donor heart is CXCL10^{-/-}. This identifies the CXCR3/CXCL10 axis as a potential drug target. Neutralization of CXCL9, a CXCR3 ligand which appears later than CXCL10, can also prolong cardiac allograft survival. It delays T-cell infiltration and acute rejection in class II MHC-disparate skin allografts. In rat, BX-471, a nonpeptide small molecule antagonist of CCR1, was reported to be effective in heart transplant rejection.

In humans, CCR5 may be important in chronic kidney allograft rejection, as in a large German kidney transplantation cohort individuals homozygous for CCR5 Δ 32 were underrepresented among patients with this outcome.

Allergic airway and intestinal disease

Chemokine receptors associated with asthma include CXCR2, CCR3, CCR4 and CCR8. CCR3 is present on eosinophils, basophils, mast cells and some Th2 T cells. CCR4 and CCR8 identify airway T cells of allergen-challenged atopic asthmatics. CCR8 knockout mice have reduced allergic airway inflammation in response to three different Th2-polarizing antigens: *Schistosoma mansoni* soluble egg antigen, ovalbumin and cockroach antigen. The situation with the CCR4 axis is unsettled, as neutralization of the CCR4 ligand CCL22 was protective in a mouse model of airway hyperreactivity and eosinophilic inflammation, but CCR4 gene knockout was not. A role for the CCR3 axis in asthma has been supported by CCL11 neutralization in guinea pig, and CCR3 gene knockout in mouse.³⁷ Only one of three studies of CCL11 knockout mice found protection, ~40% reduction in airway eosinophils in ovalbumin sensitized/challenged mice, possibly due to compensation by other CCR3 ligands. The net effect of CCR3 knockout was expected to be more profound. However, the exact phenotype depends dramatically on the specific method of sensitization and challenge owing to complex and opposite effects on eosinophil and mast cell trafficking. Thus CCR3^{-/-} mice sensitized intraperitoneally have reduced eosinophil extravasation into the lung, but an increase in mast cell homing to the trachea. The net result is a paradoxical increase in airway responsiveness to cholinergic stimulation. Mast cell mobilization is not seen after epicutaneous sensitization, and these animals have reduced airway eosinophilia on challenge and no increase in airway hyperresponsiveness. CCR6 also appears to play a role, as CCR6^{-/-} mice have decreased allergic airway inflammation in response to sensitization and challenge with cockroach antigen, which is consistent with the induction of its ligand CCL20 in this model.

Eosinophilic esophagitis has been associated with a CCL26 variant.¹⁷ Although there is no CCL26 homolog in mouse, other mouse CCR3 ligands have been implicated in a mouse model of this disease.

Cancer

Many chemokines have been detected *in situ* in tumors, and cancer cells have been shown to produce chemokines and express chemokine receptors. However, the exact role played by endogenous tumor-associated chemokines in recruiting tumor-infiltrating lymphocytes and tumor-associated macrophages and in promoting an anti-tumor immune response has not been delineated. On the contrary, there are data from mouse models suggesting that the overall effect may be to promote tumorigenesis through additional effects on cell growth, angiogenesis, apoptosis, immune evasion and metastasis.³⁸ Controlling the balance of angiogenic and angiostatic chemokines may be particularly important. This has been shown in several instances. The ratio of ELR to non-ELR CXC chemokine expression is high in nonsmall cell lung carcinoma (NSCLC) in humans. In a Scid mouse model, neutralization of endogenous tumor-derived CXCL8 (angiogenic) inhibited tumor growth and metastasis by about 50% through a decrease in tumor-derived vessel density, without directly affecting tumor cell proliferation. Chemokine receptors on tumor cells have been shown to directly mediate chemokine-dependent proliferation. Examples include CXCL1 in melanoma, and, CXCR4 in a mouse model of metastasis in breast cancer. It remains to be seen how general these effects are in other cancers.

THERAPEUTIC APPLICATIONS

CHEMOKINES AND CHEMOKINE RECEPTORS AS TARGETS FOR DRUG DEVELOPMENT

Although chemokine-targeted drug development is still in the early stages, there are already two accomplishments that deserve special mention. First, chemokine receptors are the first cytokine receptors for which potent, selective nonpeptide small molecule antagonists have been identified that work *in vivo*. Second, targeting host determinants, as in the case of CCR5 and CXCR4 in HIV/AIDS, is a new approach in the development of antimicrobial agents. Other reasonable disease indications are Duffy in *P. vivax* malaria; CXCR2 in acute neutrophil-mediated inflammation; CXCR3 and CCR2 in Th1-driven disease; CCR2 and CX3CR1 in atherosclerosis; and CCR3 and possibly CCR4 and CCR8 in Th2 diseases such as asthma.

Potent and selective nonpeptide small molecule antagonists of CXCR2, CXCR3, CXCR4, CCR1, CCR2, CCR3 and CCR5 have been reported.³⁹ These molecules share a nitrogen-rich core and appear to block ligand binding by acting at a conserved allosteric site analogous to the retinal-binding site in the transmembrane region of rhodopsin. Although small molecules taken as pills are the main goal, other blocking strategies are also under consideration, such as ribozymes, modified chemokines (e.g., amino-terminally modified versions of CCL5) and intrakines, which are modified forms of chemokines delivered by gene therapy that remain in the endoplasmic reticulum and block surface expression of newly synthesized receptors.

The fact that viral anti-chemokines typically block multiple chemokines acting at multiple receptors may hint that the most clinically effective chemokine-targeted anti-inflammatory strategy will need to provide

broad-spectrum coverage. In this regard, the viral anti-chemokines themselves may have a place therapeutically, although issues of antigenicity may be limiting. There is also proof of principle from work with a distamycin analog that broad-spectrum blockade with nonpeptide small molecules is feasible.

CHEMOKINES AS BIOLOGICAL RESPONSE MODIFIERS

Both inflammatory and homeostatic chemokines are being evaluated for therapeutic potential as biological response modifiers, acting mainly as immunomodulators or as regulators of angiogenesis. Studies to date have revealed no major problems with toxicity, and efficacy has been noted in models of cancer, inflammation, and infection. So far, clinical trials in cancer and stem cell protection have been disappointing. Chemokines are also being developed as vaccine adjuvants. They can be delivered either as pure protein, as immunomodulatory plasmids, or as recombinant protein within antigen-pulsed DC. In this application, the chemokine may act at several different steps in the immune response. For example, chemokines can be used to strengthen the trafficking of specific classes of immune cell through the site of vaccination, or to enhance the uptake of antigen by APCs, or to tilt the Th1/Th2 balance to a position that is optimal for a particular disease. Impressive efficacy in infectious disease, allergy and tumor models has been observed in rodents. Chemokine gene administration has also been shown to induce neutralizing antibody against the encoded chemokine, which is able to block immune responses and to ameliorate EAE and arthritis in rodent models.

Many chemokines, when delivered pharmacologically as recombinant proteins or by plasmid DNA or in transfected tumor cells, are able to induce immunologically mediated anti-tumor effects in mouse models and could be clinically useful. Mechanisms may differ depending on the model, but can involve recruitment of monocytes, NK cells and cytotoxic CD8 T cells to the tumor. Chemokines may also function as adjuvants in tumor antigen vaccines. Chemokine-tumor antigen fusion proteins represent a novel twist on this approach that facilitates the uptake of tumor antigens by APCs via the normal process of ligand-receptor internalization. Non-ELR CXC chemokines such as CXCL4 also exert anti-tumor effects through angiostatic mechanisms. Despite impressive anti-tumor effects in animal models, efforts to translate chemokines to human therapy have been slow. In the only published study, a phase I trial of CXCL4 in colon cancer, the chemokine was well-tolerated but no efficacy was observed.

CONCLUSION

Despite the size of the chemokine and chemokine-receptor families, and the wealth of molecular and functional information from mouse models of disease available for many members,⁴⁰ with few exceptions there is as yet little known about precise roles in clinical immunology. Blocking agents targeting chemokines and chemokine receptors are beginning to enter clinical trials for numerous disease indications, driven partly by the promise of a novel class of antiretroviral agents that target CCR5 in HIV/AIDS. The next phase of chemokine research will help determine the utility of chemokine-based therapeutics and provide greater insight into the roles played by these molecules in the pathogenesis of human disease.

Lymphocyte adhesion and trafficking

Sirpa Jalkanen, Marko Salmi

12

Proper control of the movement of lymphocytes through the body is a prerequisite for mounting an effective immune response. Lymphocyte trafficking provides the means by which the few lymphocytes that carry a specific antigen receptor have the opportunity to encounter their counter-antigen. Antigens can be introduced into the body via practically any surface that is exposed to the environment. Not only is the area to be protected vast (about 500 m² of epithelial surfaces in the skin, gut and lungs), but also the huge numbers of circulating lymphocytes (about 10¹¹), the total length of the vascular tree (>100 000 km) and the velocity of the bloodborne lymphocytes in the vessels provide formidable challenges. An elaborate process termed lymphocyte trafficking has evolved to overcome these physical constraints.^{1–3} The process relies on the basic concept of compartmentalizing specific functions into discrete anatomical organs and then connecting them by means of continuous lymphocyte recirculation. Both lymphoid and nonlymphoid organs and tissues are connected by two different types of vessels. The blood vessels transport lymphocytes into the various organs, where they have a chance to leave the blood and enter the tissue stroma. Vessels of the lymphatic system then collect the extravasated lymphocytes from these various organs and return them to the circulation (Fig. 12.1).

■ EARLY LYMPHOCYTE PRECURSOR TRAFFICKING TO THE PRIMARY LYMPHOID ORGANS ■

Lymphocyte trafficking begins at an early stage of human ontogeny, when lymphocyte precursor cells first appear and migrate into the primary lymphoid organs.⁴ The multipotent hematopoietic stem cells from the yolk sac and from the aorta–gonad–mesonephros migrate via the circulation to the liver, which is an important organ supporting B-lymphocyte production in the embryo (Chapter 8), and then into the bone marrow. Thereafter, the developmental maturation of B cells takes place solely in the bone marrow. T cells, on the other hand, require an additional migratory event, which involves the entry of marrow-derived T-cell progenitors into the thymus. These early T-cell

progenitors enter the thymus via the vessels in the cortical region. Concomitant with their differentiation and maturation via positive and negative selection, they pass from the cortex into the medulla (Chapter 9).

■ MIGRATION OF NAIVE MATURE LYMPHOCYTES FROM THE BLOOD TO THE SECONDARY LYMPHOID ORGANS ■

After completing their initial course of development, newly arisen naive B and T cells exit the primary lymphoid organs and travel through the blood into the secondary lymphoid organs. These include the peripheral lymph nodes, the organized lymphoid tissues of the gut (e.g., Peyer's patches and the appendix) and the spleen (Chapter 2). In the lymph nodes most lymphocyte trafficking from the blood to the tissues takes place in specialized postcapillary

■ KEY CONCEPTS

LYMPHOCYTES RECIRCULATE

- >> Lymphocytes recirculate continuously between blood and lymphoid organs.
- >> 80% of lymphocytes enter the lymph nodes via specialized vessels called high endothelial venules (HEV).
- >> The remaining lymphocytes enter the lymph nodes together with dendritic cells and antigens via afferent lymphatics.
- >> Lymphocytes leave the lymph nodes via efferent lymphatics.
- >> Lymphocyte recirculation allows the lymphocytes to meet their cognate antigens and other leukocyte subsets to evoke an efficient immune response.

Fig. 12.1 Lymphocyte recirculation routes under physiologic conditions. A low level of continuous antigenic transport into lymphoid organs takes place via afferent lymphatics draining the skin and the epithelium of the gut. Bloodborne lymphocytes enter the organized lymphatic tissues (lymph nodes and Peyer's patches – PP) from the circulation via the arterial tree, flow through the capillary bed, and then extravasate in the postcapillary high endothelial venules (HEV). The extravasated lymphocytes percolate through the tissue parenchyma, enter the lymphatic vessels, and are then carried via the efferent lymphatics back to the systemic circulation. Most of the venous circulation has been omitted from the Figure. Inset: an HEV. (From Salmi M, Jalkanen S. How do lymphocytes know where to go: current concepts and enigmas of lymphocyte homing. *Adv Immunol* 1997; 64: 139, with permission from Elsevier.)

venules. The venule endothelial cells exhibit a characteristic high cuboidal morphology that has given them their name: high endothelial venules (HEV).⁵ The protrusion of the surface of these endothelial cells into the vascular lumen promotes the interaction of leukocytes in the relatively low-shear venular part of the circulatory system with the endothelial surface membrane (Fig. 12.2). HEV carry many unique adhesion molecules that enable the capture of passing lymphocytes. They also have special intercellular connections that facilitate the penetration of the vessel walls by these emigrating lymphocytes. It has been estimated that more than 50% of incoming lymphocytes make transient contacts with the vascular lining in the lymph nodes, and that as many as one passing cell in four adheres to the endothelium and then extravasates into the tissue.

Antigens are gathered into these secondary lymphoid organs by a different route. Most antigens in the periphery can be taken up by dendritic cells (Chapter 7), which subsequently migrate into the secondary lymphoid organs via the afferent lymphatics.⁶ These afferent lymph channels open into the subcapsular sinus of the lymph node. Individual dendritic cells subsequently penetrate the lymphatic endothelium and emigrate into the stroma. Unbound, or free, antigens that diffuse by chance into these secondary lymphoid organs can also be captured by the professional antigen-presenting cells of the lymph nodes. Lymph nodes thus serve as traps for the immune

Fig. 12.2 Characteristic features of HEV. (A) In this immunoperoxidase staining with anti-CD31 antibody, six HEV are seen with typical plump endothelial cells. One HEV is identified by an arrow; a vessel with flat endothelium is also seen in this Figure (arrowhead). (B) In this scanning electron micrograph lymphocytes are adhering to HEV.

system, collecting lymphocytes from the blood and antigens from the lymph (Fig. 12.1). In these organs, lymphocytes percolate through the tissue in search of their cognate antigens. If a given lymphocyte does not find its antigen, it will leave the organ by entering the efferent lymphatics that drain the medullary sinuses. The frustrated cell is then transported via a major lymphatic trunk, such as the thoracic duct, back into the large systemic veins. After re-entering the circulation, the cell can then randomly gain access to another lymph node, where it has another chance to extravasate into the tissue and find its cognate antigen. One round of recirculation from the blood to the lymph node stroma, to a lymphatic vessel and then back to the blood takes about 1 day. Naïve lymphocytes continue circulating in the blood until they either find their cognate antigen or die.^{3,5}

■ ACTIVATED LYMPHOCYTES DISPLAY SELECTIVE TISSUE HOMING PATTERNS ■

In a secondary lymphoid organ a successful encounter between a lymphocyte and its cognate antigen leads to the proliferation of the cell within the organ and the maturation of its progeny.^{3, 5} Simultaneously, a process called imprinting leads to a profound change in the subsequent pattern of migration of the antigen-responsive cell. During the imprinting local dendritic cells give educational clues to the lymphocytes, which lead to changes in the chemoattractant and adhesion receptor repertoire of the lymphocytes. Although these responding cells leave the node via the lymphatics and are carried back to the systemic circulation, unlike naïve cells they no longer migrate randomly to any lymphoid tissue. Instead, imprinting primes the cells to preferentially seek the peripheral tissues in which the inciting antigen was originally ingested by the dendritic cell. In this way, selective homing of lymphocytes according to their previous history allows the organism to focus the immune response to the tissues where the effector cells can do the most good.

Among T cells, distinct pools of central and effector memory cells can be distinguished. The different profile of adhesion molecule and chemokine receptor expression allows central memory cells to continue migration through lymph nodes, whereas effector memory cells are dispersed to patrol peripheral tissues.⁷

Under normal conditions, two distinct routes of lymphocyte recirculation can be discerned.^{3, 5} One targets lymphoid cells to the peripheral lymph nodes, and the second targets them to gut-associated lymphoid tissues (GALT; Chapter 19). Although the common gut-associated lymphoid system has long been considered to include both the respiratory and the genitourinary tracts, differences in the fine specificity of lymphocyte homing between these targets do exist.

■ DISTINCT RECIRCULATION ROUTES IN SPLEEN ■

The spleen holds a unique place in the panoply of secondary lymphoid tissues.⁸ It contains more lymphocytes than all the peripheral lymph nodes put together, and the number of lymphocytes recirculating through it daily is the equivalent of the total pool of circulating lymphocytes. In the spleen, which lacks HEV, lymphocytes enter the tissue through the marginal zone sinuses, where macrophage-like cells may play an important role. Once in the splenic parenchyma, T cells accumulate in the regions surrounding the central arteriole in white pulp, a location known as the periarteriolar sheath. B cells are scattered in the corona that surrounds these T-cell areas. Most splenic lymphocytes leave the spleen via the splenic vein. The mechanisms that control the entry and exit of lymphocytes from the spleen remain incompletely understood. However, they appear to be quite distinct from those that operate in the peripheral lymph nodes and GALT.

KEY CONCEPTS

ADHESION MOLECULES IN INFLAMMATION

- >> Adhesion molecules are important in directing leukocyte traffic to sites of inflammation.
- >> Numerous inflammatory mediators upregulate and/or induce expression of several endothelial-cell adhesion molecules.
- >> Harmful inflammation can be prevented and cured by blocking the function of adhesion molecules.

■ INFLAMMATION-INDUCED CHANGES IN LEUKOCYTE TRAFFICKING ■

During an acute inflammatory response to an antigenic insult, leukocytes can migrate into all nonlymphoid tissues, which are normally virtually devoid of lymphocytes. The inflammation-induced leukocyte immigration takes place in characteristic waves.⁹ First, the polymorphonuclear leukocytes rapidly (typically within 1–4 hours) infiltrate into the inflammatory focus. They are followed by mononuclear cells (monocytes and lymphocytes). In a primary challenge it may take 3 days or more before antigen-specific immunoblasts are seen at the peripheral scene of inflammation. However, a secondary response by memory lymphocytes typically has a much shorter lag period. Different CD4 T-helper subpopulations (Chapters 9 and 17), CD8 T-cytotoxic cells (Chapter 18), and regulatory T cells (Chapter 16) can all enter the inflamed tissue using basically the same mechanisms, although the ratio of these populations and the individual molecules employed may vary. Successful resolution of an inflammatory reaction appears to also be dependent on a coordinated program involving lipoxins, resolvins and protectins, all of which serve to halt cell recruitment and initiate apoptosis.¹⁰

The normal vascular endothelium in nonlymphoid tissues has a flat, inactive morphology. With inflammation, a series of events renders postcapillary venules in these tissues capable of binding lymphocytes. The most important changes are due to the proadhesive effects of a multitude of proinflammatory cytokines that are released by a variety of cell types after being subjected to inflammatory stimuli.⁹

If inflammation becomes chronic, marked histological manifestations become apparent in affected nonlymphoid tissues.¹¹ Most notably, the venules in these chronically inflamed tissues acquire many of the characteristics of HEV. Also, immigrating lymphocytes can form lymphoid follicles that resemble those seen in lymph nodes. These alterations have consequences for lymphocyte recirculation pathways. For example, the inflamed skin display characteristics of lymphocyte homing that are clearly distinct from those of either mucosal or peripheral lymph node systems.¹²

MOLECULAR MECHANISMS INVOLVED IN LEUKOCYTE EXTRAVASATION FROM THE BLOOD INTO THE TISSUES

THE ADHESION CASCADE

Dynamic interactions between leukocytes and endothelial cells can be observed both *in vitro* and *in vivo*. By means of intravital microscopy, for example, leukocyte adhesion can be followed *in vivo* in experimental animals and even in human tissues (Fig. 12.3). Leukocyte–endothelial-cell interaction during the extravasation cascade can be divided into a series of phases, or steps, that all leukocyte subtypes are thought to follow (Fig. 12.4).^{2,3} First, the leukocytes marginate out of

the main bloodstream and begin to tether and roll on the endothelial cell surface. This step is mediated primarily by selectin adhesion molecules and their mucin-like counter-receptors. This slow-velocity movement culminates in an activation phase, during which the leukocyte chemokine receptors transmit activation signals by recognizing their chemokine ligands presented on the endothelial-cell surface. This leads to avidity and/or affinity changes in leukocyte integrins that bind the leukocytes firmly to their immunoglobulin superfamily ligands on the endothelial cells. The lymphocytes then begin to transmigrate through the endothelium, a process that also involves leukocyte integrins and other molecules. Leukocytes diapedese between the endothelial cells through the endothelial cell junction, which opens transiently and subsequently closes.¹³ This process requires proteinases, such as matrix metalloproteinase-2 (MMP-2), which is induced in T cells upon adhesion to endothelial cells, as well as other, as yet to be defined, repair mechanisms that subsequently close the path of transmigration. However, leukocytes can also migrate through the endothelial cells in a subtype-specific fashion. For example, polymorphonuclear leukocytes prefer entering via the inter-endothelial junctions, whereas nonactivated lymphocytes may choose the transcellular route.¹⁴

An additional complexity to the extravasation system is created by the fact that certain endothelial molecules involved in the adhesion cascade show organ-specific expression patterns. Analogously, leukocyte-associated homing molecules display subtype-specific expression profiles. Therefore, only those leukocytes that have the proper set of molecules on their surface can enter a particular tissue, because the entering leukocyte has to find a correct endothelial partner molecule at each step of the adhesion cascade. Thus, leukocyte–endothelial-cell interaction takes place in a well-coordinated multistep fashion, in which every step must be properly executed in order before the leukocyte can be guided into the tissue. The multistep nature of the leukocyte adhesion cascade is thus reminiscent of the cascades involved in blood clotting and complement-mediated killing.

KEY CONCEPTS

LEUKOCYTE-ENDOTHELIAL INTERACTIONS

- >> Leukocytes interact with the vessel wall in a multistep fashion, using several leukocyte surface molecules that recognize their counter-receptors on endothelial cells.
- >> The rolling and tethering of leukocytes on the vessel wall is mediated by selectins.
- >> Chemokines and their receptors are needed to activate leukocyte integrins.
- >> Only activated integrins are able to mediate firm adhesion between leukocytes and endothelium.
- >> The transmigration of leukocytes into the tissues requires proteinases and repair mechanisms.

Fig. 12.3 Intravital microscopy of mesenteric vessels. In these video frames taken at indicated intervals from the same field, a vein, an artery, leukocytes and the transparent mesenteric membrane are seen. Within the vein rolling and adherent leukocytes are visible, whereas no such cells are seen in the artery. Leukocyte 1 is attached to the vessel wall and leukocyte 2 is slowly rolling. Compare the locations of these cells in A and B to stationary leukocytes outside the vessels. Leukocyte 1 is at the same location in both panels, whereas leukocyte 2 has moved a distance corresponding to roughly the length of its diameter. Under normal conditions, freely flowing cells move so fast that they cannot be visualized. However, in panel C the flow has been transiently stopped. Under this static condition, the large number of hematopoietic cells (mainly erythrocytes) traveling within the bloodstream can be seen. (Courtesy of S. Tohka, University of Turku, Finland.)

RECEPTORS AND THEIR LIGANDS IN LEUKOCYTE-ENDOTHELIAL-CELL INTERACTION

A variety of molecules belonging to several molecular families are expressed on both leukocyte and endothelial-cell surfaces and participate in the complex extravasation process.⁵ Most of these molecules exert their function in successive, but overlapping, phases of the adhesion cascade. In addition, proper functioning of multiple intracellular signaling molecules is needed for execution of a successful extravasation.¹⁵ In the following section, only the best-known surface molecules in this process are discussed (Fig. 12.5). A summary of the phenotypes exhibited by mice that are deficient for these molecules is presented in Table 12.1.

Selectins and their ligands

Three members of the selectin family mediate leukocyte trafficking. L-selectin is expressed on several leukocyte subpopulations. E-selectin is expressed on endothelium, and P-selectin is expressed on both platelets and endothelium. An important structural feature of selectins is the presence of a terminal lectin domain that is used to bind to their counter-receptors. The counter-receptor is typically decorated by a sialyl Lewis X (sLeX) carbohydrate, which is a prototype recognition domain for selectins in general.¹⁶ The interaction between selectins and their counter-receptors is transient and weak, which allows leukocytes effectively to form and break contacts with endothelium during tethering and rolling under shear stress.

L-selectin preferentially mediates lymphocyte migration to peripheral lymph nodes. However, it also participates in the homing of lymphocytes to organized MALT, e.g., Peyer's patches (Chapter 19). L-selectin is also an important contributor to the process of leukocyte trafficking to sites of inflammation. Peripheral lymph node addressins (PNAd) are the best-characterized counter-receptors for L-selectin. This group consists of at least six different molecules that are decorated with a sulfated and

fucosylated sLeX that serves as a recognition motif for L-selectin. PNAds include glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1), CD34, podocalyxin, endomucin, nepmucin, and mucosal addressin cell adhesion molecule-1 (MAdCAM-1). MAdCAM-1 is decorated with recognition epitopes for L-selectin on HEV in the organized lymphoid areas of the gut, but not on the flat-walled vessels in lamina propria. The importance of post-translational carbohydrate modifications for the function of selectin ligands has been well demonstrated in knockout mice deficient for fucosyl, glucosaminyl, galactosyl, sialyl or sulfotransferases. For example, mice with a targeted disruption of fucosyltransferase VII (Fuc-TVII) are unable to glycosylate L-selectin ligands appropriately. These mice exhibit severe defects in lymphocyte homing and in the extravasation of leukocytes to sites of inflammation. In contrast, core 2 β 1,6-*N*-acetylglucosaminyltransferase (C2 β GlcNAcT) knockout mice that have deficient glycosylation of their P- and E-selectin ligands demonstrate normal lymphocyte homing to lymph nodes, but impaired leukocyte trafficking to sites of inflammation.¹⁶ Interestingly, L-selectin also facilitates entry of leukocytes into the tissues by mediating leukocyte tethering and rolling of endothelium-bound leukocytes by binding to P-selectin glycoprotein ligand-1 (PSGL-1).

E-selectin and P-selectin are inflammation-inducible molecules. Within minutes, P-selectin can be translocated from intracellular storage granules onto the endothelial cell surface, where it binds to its leukocyte receptor, PSGL-1 (Fig. 12.5). P-selectin and PSGL-1 mediate rolling at early time points during inflammation. Platelet P-selectin can facilitate lymphocyte entry into the tissues, because it can simultaneously bind to PNAd on endothelium and PSGL-1 on lymphocytes. E-selectin upregulation requires new protein synthesis. It is maximally expressed about 4 hours after the induction of inflammation. E-selectin is needed for slow rolling of leukocytes. It also has an affinity towards PSGL-1, as well as a specific glycoform of PSGL-1, cutaneous lymphocyte antigen (CLA). CLA specifically directs lymphocyte trafficking to inflamed skin. In addition to PSGL-1, E-selectin has a more private leukocyte receptor called E-selectin

Fig. 12.4 The multistep cascade of lymphocyte extravasation. The bloodborne cell makes transient initial contacts with endothelial cells, which leads to the cell rolling along the vascular lining. If the cell becomes activated, it can subsequently adhere firmly to the endothelial cells, seek for interendothelial junctions, and then migrate through the basement membrane into the tissue. The contribution of major superfamilies of adhesion-associated molecules at each step is depicted below. E, endothelial layer; Bm, basement membrane.

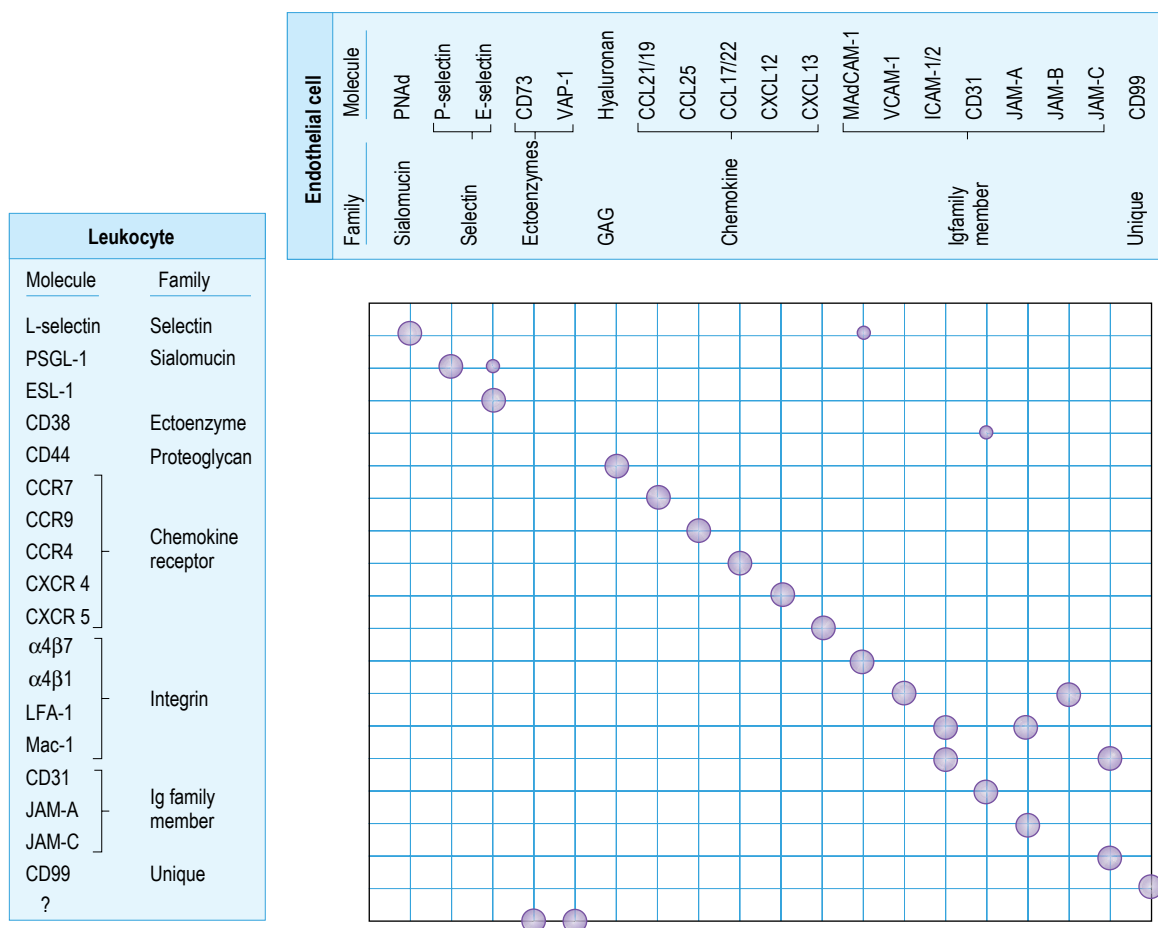

Fig. 12.5 Adhesion molecules mediating leukocyte traffic. The most relevant proteins involved in leukocyte–endothelial-cell interactions are shown as receptor–ligand pairs. GAG, glycosaminoglycan.

ligand-1 (ESL-1) (Fig. 12.5).¹⁷ Mice deficient for both E- and P-selectin have more drastic defects in their rolling and leukocyte migration to sites of inflammation than could have been anticipated from the mice deficient in only one of the two selectins. This suggests that E- and P-selectins have overlapping functions and can compensate for each other.

Chemokines and their receptors

Chemotactic cytokines and their receptors (Chapter 11) are grouped into four different families based on their primary protein structure. The families are defined by a cysteine signature motif – CXC, CC, C and CX3C – where C is a cysteine and X any amino acid residue.¹⁸ Most chemokines are small, soluble heparin-binding chemoattractants. The relevant chemokines for leukocyte extravasation are presented to bloodborne lymphocytes by proteoglycan molecules present on endothelial cell surfaces. During the adhesion cascade they activate integrins by signaling via serpentine receptors, which are pertussis-toxin sensitive and G-protein linked.

Different leukocyte subsets bear their own distinct sets of receptors, which enable them to respond to chemokines presented on the vascular

endothelium as well as within the tissues. For example, CCL21 and CCL19 are preferentially expressed by HEV that are found in interfollicular areas within a lymph node. They preferentially attract T cells bearing the CCR7 receptor, and thus draw T lymphocytes from the blood and into these areas. Fractalkine, a CX3C chemokine, can be produced in either a soluble or a membrane-anchored form. It can be found on HEV in peripheral lymph nodes and has potent chemoattractant activity for T cells. The major attractants for B cells are CXCL12 and CXCL13. Although many chemokines are present in different organs in the body, some selectivity in their expression can guide tissue-selective leukocyte trafficking. For example, CCL25 attracts CCR9 positive lymphocytes to the small intestine, and CCL17/CCL22 attract CCR4-bearing lymphocytes to the skin.

Integrins and their immunoglobulin superfamily ligands

Integrins are a large family of heterodimeric molecules consisting of an α and a β chain.¹⁹ Traditionally they are thought to mediate firm adhesion between leukocytes and endothelial cells, although in specific low-shear

Table 12.1 Phenotypes of the mice deficient in homing-associated molecules

Molecule	Main abnormalities in leukocyte trafficking
L-selectin	Impaired lymphocyte homing to peripheral lymph nodes
E-selectin	Increased velocity of rolling leukocytes
P-selectin	Decreased leukocyte rolling at early stages of inflammation
PSGL-1	Decreased leukocyte rolling at early stages of inflammation
ICAM-1	Impaired neutrophil migration to sites of inflammation
ICAM-2	Delayed eosinophil accumulation in the airway lumen in allergy, impaired neutrophil transmigration
VCAM-1	Embryonic lethal
CD31	Deficient migration through basement membrane
JAM-A	Increased dendritic cell homing to lymph nodes and reduced transendothelial migration
S1P ₁	Embryonic lethal
CD11a	Reduced lymphocyte trafficking to peripheral lymph nodes and to Peyer's patches
CD11b	Decreased leukocyte trafficking to sites of inflammation Decreased neutrophil emigration in ischemia/reperfusion injury
β_2 -integrin	No neutrophil emigration into the skin, normal emigration into inflamed peritoneum and increased migration into inflamed lung
α_4 -integrin	Embryonic lethal, chimeric mice have reduced lymphocyte homing into Peyer's patches
β_7 -integrin	Impaired lymphocyte migration into Peyer's patches
CD44	Decreased lymphocyte migration to peripheral lymph nodes and thymus
VAP-1	Faster rolling, decreased firm adhesion and transmigration and diminished leukocyte infiltration to sites of inflammation
CD73	Increased leukocyte traffic to sites of inflammation in ischemia
CD38	Defective chemotaxis of granulocytes and dendritic cells in severe inflammations
CCR9	Reduced number of intraepithelial T cells and IgA-positive plasma cells in lamina propria
CCR7	Defective lymphocyte entry to lymph nodes and formation of T-cell areas
CCL19/CCL21	Impaired homing of lymphocytes (especially T cells) to lymph nodes
CXCR5/CXCL13	Defect in the formation of follicles in the lymph nodes
CXCR4	Aberrant B-cell follicles
CCR4	Prolonged graft survival due to reduced T-cell trafficking

conditions they can also participate in rolling. With regard to leukocyte trafficking, the most important integrins are $\alpha_4\beta_7$, LFA-1 and $\alpha_4\beta_1$. $\alpha_4\beta_7$ is a principal homing receptor for lymphocyte trafficking to mucosa-associated lymphatic tissues. It binds to MAdCAM-1 on HEV in organized mucosal lymphatic tissues, such as Peyer's patches and appendix, and to flat-walled venules in the lamina propria.

α_4 -Integrin can also pair with a β_1 chain to form an $\alpha_4\beta_1$ dimer, which lymphocytes utilize primarily in inflammatory conditions. It binds to endothelial vascular cell adhesion molecule-1 (VCAM-1) on endothelium.

Lymphocyte function-associated antigen-1 (LFA-1/CD11a/CD18) is a member of the group of leukocyte integrins that contain a unique α chain (CD11 a, b, c and d), but share a common β chain (β_2 /CD18). LFA-1 is present on practically all leukocyte subsets. It interacts with its counter-receptors, intercellular adhesion molecules (ICAM-1 and ICAM-2) on the endothelial cell surface (Fig. 12.5). ICAM-1 is upregulated at sites of inflammation, whereas ICAM-2 is constitutively present

on vascular endothelium. To be functional, LFA-1 needs to be activated. Activation of LFA-1 is thought to be primarily a product of chemokine signaling. However, alternative activation pathways include triggering through glycosyl-phosphatidylinositol (GPI)-linked molecules, CD44, as well as other costimulatory lymphocyte surface molecules.¹⁵ LFA-1-dependent pathways display no significant organ specificity in their function. Mac-1 (CD11b/CD18) is also involved in leukocyte migration, although its contribution is overshadowed by LFA-1. Like LFA-1, Mac-1 uses ICAM-1 and ICAM-2 as its ligands (Fig. 12.5).

Other homing-associated molecules

Several other molecules belonging to various molecular families also participate in the adhesion cascade. CD44 is a multifunctional proteoglycan that is found on a large variety of different cell types.²⁰ Using endothelial hyaluronan as its ligand, it mediates lymphocyte rolling. It can form bimolecular complexes with $\alpha_4\beta_1$ that strengthens leukocyte-endothelial-cell

interaction. *In vivo* inhibition studies using function-blocking antibodies indicate that CD44 plays an important role in directing lymphocyte trafficking to sites of inflammation, e.g., skin and joints.

CD31, a member of the immunoglobulin superfamily, is found on many subsets of lymphocytes and in the continuous endothelium of all vessel types. It is expressed primarily at the intercellular junctions and is involved in a stimulus-specific manner in transmigration, especially through the endothelial basement membrane. Other molecules involved in the transmigration process are CD99 and junctional adhesion molecules A and C, which are expressed both on leukocytes and endothelial cells. These molecules interact sequentially in a homotypic fashion during diapedesis. In addition, endothelial JAM-A can use LFA-1, JAM-C may utilize Mac-1, and JAM-B uses $\alpha_4\beta_1$ as leukocyte ligands.

The role of ectoenzymes in the adhesion cascade has been recently recognized.²¹ Vascular adhesion protein-1 (VAP-1), CD73, and CD38 have well established roles in leukocyte trafficking. Owing to their enzymatic properties, they can rapidly modify adhesive interactions and modulate the microenvironment. VAP-1 is a homodimeric sialoglycoprotein that, under conditions of inflammation, is rapidly translocated on to the endothelial cell surface. It mediates early phases of leukocyte interaction with endothelium, as well as transmigration. Besides its adhesive

function, it also possesses an amine oxidase activity that can produce potent immunomodulators such as H_2O_2 and aldehyde as end products. CD73 is present both on a subpopulation of lymphocytes and on endothelium. It is an ectonucleotidase. The main product of its enzymatic activity in dephosphorylation of AMP is adenosine, which is highly anti-inflammatory in nature. Endothelial CD73 may also have a counter-receptor on the lymphocyte surface, because lymphocyte binding to endothelium inhibits the enzymatic activity of CD73. This facilitates the extravasation process of the lymphocyte. CD38, an ADP-ribosyl cyclase, is expressed on most lymphoid cells and can use CD31 as its endothelial cell ligand. Via its enzymatic activity it regulates calcium fluxes and the sensitivity of leukocytes to chemokine signals.

INTRAORGAN LYMPHOCYTE LOCALIZATION

Following its extravasation from the blood vessels, a lymphocyte needs to interact with several matrix molecules, such as fibronectin, laminin and collagens. Adhesive interactions between a lymphocyte and the extracellular matrix molecules are largely mediated by β_1 -integrins, although

Fig. 12.6 The role of chemokines in entrance and intraorgan localization of lymphocytes. CCL19 and CCL21 are involved in T-lymphocyte entrance into the lymph node via HEV. They also guide T cells to the interfollicular areas within the node. In contrast, CXCL12 and CXCL13 attract B lymphocytes on the vessel wall and direct their localization within the follicles.

lymphocytes can also use CD44 to interact with fibronectin and collagens. The directional movement and the final localization of a lymphocyte within the tissues are controlled by chemokines.^{9, 18, 22} Modern two-photon imaging has provided detailed information about the kinetics and directionality of lymphocyte movement in living tissues.²³

Besides directing the entry of T cells into the tissues, CCL21 and CCL19 also determine the final destination of the T lymphocyte within lymph nodes, spleen and Peyer's patches. CCL19 and CCL21 produced by stromal cells in the T-cell areas within the lymphoid tissues guide the T lymphocyte into the interfollicular space. In an analogous manner, B-cell-attracting chemokine-1 CXCL13 is produced by a subset of follicular dendritic cells found in secondary lymphoid organs. It attracts B cells possessing CXCR5 to the light zone of the follicles. CXCL12, on the other hand, guides CXCR4 positive B cells to the dark zone (Fig. 12.6).

Correct localization of a lymphocyte and an antigen-presenting cell within the lymph node is a prerequisite for an optimal immune response. Dendritic cells that carry antigens from the peripheral tissues into the lymph node enter the node via afferent lymphatic vessels (Fig. 12.6). An interaction between the dendritic cell and the T cell in the T-cell area is then crucial for T-cell activation. B-cell collaboration with T cells is ensured by upregulation of CXCR5 expression on a subpopulation of T cells, and of CCR7 on certain B cells that allow the movement of these cells to the boundary of the B- and T-cell zones. The importance of CCL21 and CCL19 in lymphocyte trafficking is demonstrated by a spontaneous mutant mouse strain, *p/l*, which has reduced expression of these chemokines. In these mice, both lymphocyte entry via HEV and the organization of T-cell areas within lymph nodes are defective, which is recapitulated in CCR7 knockout mice. CCL21/CCL19 and CXCL12/CXCL13 are currently the best-known determinants of lymphocyte localization within lymphoid tissues, although several other chemokines are also needed for optimal encounters between various cell populations in order to create a crisp immune response.

CELL TRAFFICKING WITHIN LYMPHATICS

Although leukocyte trafficking within the lymphatics is an essential part of the recirculation process and the immune response in general, very little is known about the molecular mechanisms that regulate

this tightly controlled and cell type-selective migration. CCL21 on lymphatic endothelium attracts CCR7-positive dendritic cells and lymphocytes into the afferent lymphatics and thence to the draining lymph nodes. JAM-A may also control the traffic of dendritic cells, as dendritic cells defective for JAM-A show increased motility and enhanced trafficking via the afferent lymphatics into the draining lymph nodes. Furthermore, certain adhesion molecules, such as macrophage mannose receptor and common lymphatic endothelial and vascular endothelial receptor-1 (CLEVER-1), may mediate lymphocyte migration into the lymphatics, as lymphocytes adhere to lymphatic vessels via these molecules in *in vitro* assays.^{5, 14} Sphingosine 1 phosphate receptor 1 (S1P₁), which is expressed in many different cell types, also participates in lymphocyte exit into the lymphatics. Although its absence leads to defects in vascular development and embryonic lethality, studies of conditional knockout mice have shown that lymphocytes lacking S1P₁ can enter the lymph nodes normally. However, they are not able to exit from the lymph nodes into the efferent lymphatics. Additional studies indicate that S1P₁ may control lymphocyte trafficking by regulating endothelial permeability and/or suppressing lymphocyte chemotaxis in S1P gradients.^{22, 24}

CLINICAL IMPLICATIONS

Leukocyte trafficking plays a pivotal role in the pathogenesis of all infectious and inflammatory diseases. It is essential for mounting a proper immune response against an invading microbe. However, in many other cases inappropriate leukocyte migration also causes tissue destruction. Here we have chosen a few representative examples to illustrate some of the general principles.

IMMUNODEFICIENCIES

Various defects in leukocyte trafficking have been identified during the past two decades. Leukocytes from patients with Wiskott-Aldrich syndrome, for example, show reduced migration to chemokines CCL2, CCL3 and CXCL12 owing to a mutation in the gene encoding an intracellular WAS protein responsible for proper cytoskeletal organization of the hematopoietic cells. Mutations of CXCR4 in WHIM (warts, hypogammaglobulinemia, infections and myelokathexis) patients lead to an enhanced chemotactic response to CXCL12 expressed on bone marrow endothelium and leukocyte accumulation in the bone marrow.²⁵ A single

Table 12.2 Clinical features of immunodeficient patients with abnormalities in homing-associated molecules

	LADI	LADII	LADIII
Clinical manifestation			
Recurrent bacterial infections	+++	+	+++
Neutrophilia	yes	yes	yes
Developmental abnormalities	no	Yes	no
Laboratory findings			
CD18 expression	Marked decrease or absence	Normal or slightly decreased	Normal
sLex expression	Normal	Absent	Normal
Neutrophil rolling	Normal	Marked decrease	Normal
Neutrophil firm adherence	Marked decrease	Normal	Marked decrease

case of inherited dysfunction of E-selectin has also been reported. The patient had recurrent infections but did not demonstrate neutrophilia. She could not synthesize E-selectin on endothelium, although her serum level of soluble E-selectin was increased.

Three different forms of adhesion defect in integrins lead to poor or total lack of homing of certain leukocyte populations.^{25, 26} Their typical features are listed in Table 12.2. These diseases are extremely rare, but they recapitulate beautifully in humans the basic principles of leukocyte trafficking first deciphered in animal models.

LAD I and LAD I variant (LAD III)

Patients with leukocyte adhesion defect-1 (LAD-1) have defects in the synthesis, pairing or expression of β_2 -integrins.²⁷ The severe form leads to the total or almost total absence of CD11a/CD18 (LFA-1), CD11b/CD18 (Mac-1), CD11c/CD18 and CD11d/CD18. Although these patients exhibit neutrophilia, they suffer from severe recurrent bacterial infections owing to defects in leukocyte extravasation into sites of inflammation. They usually die young. Patients suffering from a milder form of LAD-1 (<10% of normal β_2 -integrins) demonstrate impairment in leukocyte migration and suffer from frequent infections as well, but usually survive until adulthood. In these patients lymphocyte migration to inflammatory sites is close to normal, probably because lymphocytes can utilize the VLA-4-VCAM-1 pathway to compensate for the lack of β_2 -integrins.

LAD-1 variants have also been described.^{26, 27} In one group, modestly reduced β_2 -integrin expression has been associated with mutations which create heterodimers that do not bind ligands. A second group of LAD I variants (also known as LAD III) involves defective inside-out signaling. In these patients activation of multiple leukocyte integrins, including LFA-1 and VLA-4, by chemokine-triggered G-protein-coupled signals is genetically defective. Concurrent defects in platelet integrins lead to a bleeding diathesis. In all types of LAD I, granulocytes typically show normal rolling, but failure to arrest on endothelial cells.

LAD II

LAD II patients suffer from several abnormalities, including recurrent infections, neutrophilia, impaired pus formation, mental retardation, growth defects and deficiency in H blood group antigen.²⁷ The cause of the disease is impaired transport of GDP-fucose from the cytoplasm to the Golgi lumen as a result of mutations in a GDP-fucose transporter. The defect leads to impaired modification of selectin ligands, notably that of PSGL-1, with fucose. Consequently, they demonstrate a marked decrease in leukocyte rolling under flow conditions. Interestingly, some patients respond to treatment with oral fucose.

DISEASES OF AUTOIMMUNITY

Multiple sclerosis

Migration of lymphocytes through the blood-brain barrier into the central nervous system is a key pathogenetic event that occurs during the development of multiple sclerosis (MS) and its widely used animal model, experimental allergic encephalomyelitis (EAE). *In vivo* animal

studies have shown that the disease course can be dramatically altered by blocking the function of leukocyte α_4 -integrin.²⁸ This treatment is able to prevent the disease and even reverse the paralytic disease and lymphocytic infiltrations in the brain. Antibodies against $\alpha_4\beta_1$ show this remarkable efficacy even if started a month after the onset of the clinical disease. Certain EAE models can also be blocked by targeting the α_4 -integrin ligand VCAM-1, or by blocking the function of CD44. In contrast, blocking of many other adhesion molecules, such as L-selectin, PSGL-1, E- and P-selectin and ICAM-1, fail to yield a consistent effect on EAE. Use of lymphocytes from MS patients in murine models has confirmed the importance of $\alpha_4\beta_1$ -mediated leukocyte interaction in EAE brain, but have also revealed a role for PSGL-1. It should also be noted that although $\alpha_4\beta_1$ -integrin is very important for lymphocyte homing to brain, it is not a brain-specific zip code, as it is also involved in leukocyte trafficking to other organs, such as pancreas and gut.

TRANSPLANT REJECTION

In all forms of rejection, activation of vascular endothelium of the graft with the ensuing lymphocyte infiltration is a critical parameter. In heart transplantation, for example, multiple endothelial adhesion molecules (such as P-selectin, ICAM-1 and PNAd) normally absent from the organ are rapidly induced in a rejected organ. *In vivo* studies have shown that blocking the function of these molecules prevents the unwanted binding of lymphocytes to the graft.²⁹ For example, in rodent allograft models rejection is significantly reduced if lymphocyte LFA-1 and endothelial ICAM-1 are rendered nonfunctional by monoclonal antibodies or by disruption of these molecules through gene deletion. The chemoattractant system has also been extensively targeted for inhibiting lymphocyte influx into transplants. For instance, FTY720, a small molecule that inhibits S1P₁ receptor, promotes long-term graft survival in murine models.

ISCHEMIA-REPERFUSION INJURY

When blood flow is restored to the ischemic organ a massive influx of granulocytes into the hypoxic tissue can be seen. This ischemia-reperfusion injury is due to the activation of the endothelial cells in the insulted organ. In many cases it has been shown that depletion of circulating neutrophils, or blockage of their entry into the ischemic tissue through anti-adhesive therapy, can reduce tissue necrosis by up to 50% and prevent the death of cells in the zone of reversibly damaged tissue.³⁰ Myocardial ischemia-reperfusion injury, for example, is alleviated in CD18, ICAM-1, P-selectin and E-selectin-deficient mice. In many cases similar results have been obtained by using antibodies to block the function of these adhesion proteins, which are induced in the ischemic tissue.

CANCER

Lymphocyte trafficking can be harnessed to improve the outcome of cellular immunotherapy against cancer.³¹ Infusion of activated or genetically modified effector T cells would benefit from a more effective targeting of the cells into the tumor. On the other hand, anti-adhesive therapies targeting inappropriate accumulation of regulatory T cells in the tumor would also enhance anti-cancer immune responses.³²

THERAPEUTIC PRINCIPLES

- >> Pro-adhesive strategies are mainly developed using gene therapy.
- >> Inappropriate inflammation associated with many diseases can be dampened by anti-adhesive therapeutics.
- >> Humanized, function-blocking monoclonal antibodies are effective anti-adhesive molecules.
- >> Cell migration can also be blocked by ligand and receptor analogs, small molecule inhibitors and genetic means (e.g., RNA interference).

ADHESION MOLECULES AS DIAGNOSTIC TARGETS

Immunodeficiency disorders

In classic LAD I deficiency a definitive diagnosis can be established by flow-cytometric analysis of immunofluorescent-stained CD18 integrin on blood leukocytes.²⁷ In normal individuals practically all peripheral blood lymphocytes are CD18 positive. In severe cases of LAD I deficiency there is a complete absence of this adhesion molecule, whereas in moderate deficiency about 1–10% of control levels is seen. Diagnosis of LAD III requires activation of the cells, the use of mAb that recognize specific activation epitopes, or functional assays.

LAD II can be diagnosed with commercially available antibodies by documenting a lack of fucosylated adhesion molecules, e.g., abnormal expression of sLeX on blood leukocytes.

Soluble adhesion molecules

Most adhesion molecules are found in soluble forms in body fluids. They can be produced by alternative splicing of the mRNA leading to the lack of transmembrane anchors, by proteolytic cleavage of cell bound proteins by various sheddases (proteases), or by cleavage of the GPI linkage. The soluble forms can either function as molecular sinks, competing for their specific ligand(s) with the membrane-bound forms, or trigger biological responses by interacting with their ligand-bearing cells.

The availability of commercial kits for measuring the levels of soluble adhesion molecules has led to numerous reports describing an increase or a decrease of certain adhesion molecules in different diseases. In most cases there appears to be little or no additional diagnostic or predictive value derived from the use of these tests compared to more traditional parameters of inflammation activity. Therefore, at present, the indications for measurements of soluble adhesion molecules, or chemokines, in inflammatory and cancerous diseases remain to be defined.

Imaging

The use of neutrophil scans or radioactively labeled nonspecific molecules to localize inflammatory foci is not satisfactory in terms of timing, expense, biohazards, specificity or sensitivity. Hence, there have been trials to radioactively or nonradioactively label monoclonal antibodies that recognize endothelial adhesion molecules, infuse them intravenously, and

CLINICAL PEARLS

- >> Efalizumab, a humanized antibody against leukocyte integrin CD11a, is efficacious in the treatment of psoriasis.
- >> Blocking of α_4 -integrin with natalizumab can ameliorate disease activity in multiple sclerosis.

follow their accumulation by appropriate imaging devices.³³ Inflammation-inducible molecules such as E-selectin and MadCAM-1 have been used as target antigens. In the case of radioactively labeled E-selectin antibodies, the utility of this approach has been verified in patients.

THERAPEUTIC APPLICATION OF ADHESION MODULATING THERAPIES

Pro- and anti-adhesive therapies have long been an obvious pharmaceutical goal in the field of leukocyte trafficking. Inflammation-promoting strategies would be beneficial in diseases such as immune deficiencies, persistent infections and cancer. Moreover, pro-adhesive control of lymphocyte traffic would benefit areas such as vaccine development and bone-marrow cell transplantation. In fact, lymphocyte recirculation routes have been already empirically exploited by choosing optimal primary and secondary vaccination regimens at different anatomical locations. Anti-adhesive therapy, on the other hand, can be seen as a form of treatment applicable to all disease categories involving an inflammatory component. In addition, it could provide novel precision drugs individually tailored for organ-specific inflammatory disorders, which would be predicted to diminish the problems of generalized immunosuppression.

FROM ANTIBODIES TO SMALL MOLECULAR DRUGS

A number of specific antagonists of adhesion molecules have been developed.³⁴ Function-blocking monoclonal antibodies have often been the drug candidates used for proof-of-principle experiments. These include both chimeric and fully humanized antibodies against important adhesion molecules and chemokines. In parallel, recombinant ligand or receptor analogs have been developed. Ultimately, knowledge of the structure of the adhesion molecules has allowed the design of rational, small molecular drugs such as those affecting the conformational state of leukocyte integrins.³⁵ Recently, the ability to modulate mRNA expression of adhesion molecules through RNAi has added another potential tool to the pharmaceutical armamentarium.

Although all these forms of therapy have been enormously successful in a panoply of different animal models, transfer to the clinic has been difficult. However, recently a small number of very potent drugs targeting adhesion molecules have been introduced.

ADHESION-MODULATING DRUGS IN CLINICAL USE

The first two selective adhesion molecule inhibitors (SAM) are efalizumab and natalizumab. Efalizumab is a humanized, function-blocking antibody directed against CD11a. It has been used in patients with plaque psoriasis. Weekly subcutaneous injections of the antibody have

improved the disease score by more than 75% in 22–39% of patients, compared to a similar response in 5% of placebo-treated patients.³⁶ In addition, in >30% of patients other clinical endpoints, including physician-assessed disease activity, have improved significantly.

The way for natalizumab, a humanized anti- α_4 -integrin antibody, was paved by the excellent results of α_4 blocking in EAE (see above). In patients with relapsing multiple sclerosis a monthly intravenous injection of natalizumab has led to >90% fewer lesions than with placebo.³⁷ The risk of sustained progression of disability has been reduced by >40%. Also the rate of clinical relapses has been diminished by almost 70%. Even in patients who relapsed in spite of β -interferon treatment, the addition of natalizumab to the treatment regimen reduced the formation of new or enlarging lesions by >80% and diminished the number of clinical relapses by about 50%. These data indicate that natalizumab may be more effective in the treatment of multiple sclerosis than any of the currently employed therapies. Because α_4 can also pair with β_7 , natalizumab has also been tested in patients with Crohn's disease. A subpopulation of these patients have responded favorably to long-term treatment.

At the time this chapter was written, approximately 3500 patients had been treated with efalizumab and about 10 000 had received natalizumab. Compared to placebo groups, only one type of serious adverse reaction was associated with therapy. During natalizumab treatment, reactivation of a polyoma JC virus led to three cases of multifocal leukoencephalopathy, two of which were fatal. Close follow-up studies revealed that the risk of this complication is about 1 in 1000 during 1–2 years of natalizumab treatment. Reports of potentially deadly complications led to the temporary withdrawal of natalizumab from the market, but the benefits of the therapy were recently thought to outweigh the potential risks, and the drug was returned to the market. Apart from the incidence of leukoencephalopathy, only fatigue and allergic reactions have been more common in natalizumab-treated patients than in controls, and no adverse reactions specific to efalizumab have been reported. Thus, it is encouraging that targeted interference with an adhesion molecule has not been shown to lead to a generalized immunosuppression and a concomitant increase in infections. However, other potential problems with SAM therapy include rebound type of exacerbation of the disease after discontinuation of the drugs, and the induction of an immune response against the antibodies, which blunts the efficacy of the therapy. Finally, it should be emphasized that both efalizumab and natalizumab may have anti-inflammatory properties, such as an ability to block T-cell activation, that are not related to their central role in leukocyte recirculation. In any case these two antibodies are the first evidence that the understanding of lymphocyte trafficking can be successfully harnessed in clinical medicine.

T-cell activation and tolerance

Jonathan S. Maltzman, Erik J. Peterson, Gary Koretzky

13

Activation of T lymphocytes during an immune response triggers a series of programmed gene regulation, proliferation, differentiation, and effector functions. These programs are designed to allow the immune system to react against foreign antigens without initiating self-reactivity or autoimmunity. Each of these functions is fully dependent on signals originating outside the cell that are recognized by cell surface receptors and then translated by means of a series of biochemical alterations within the cell. This chapter will discuss signals through one of the most studied of these receptors, the antigen-specific T-cell receptor (TCR) complex. It will address how the quality of this signal, in combination with additional co-stimulatory signals, can produce either productive

activation or immune tolerance. It will also discuss how abnormal signaling can contribute to T-cell dysfunction and disease (Table 13.1).

■ THE T-CELL ANTIGEN RECEPTOR COMPLEX ■

The TCR complex consists of a ligand-binding α/β or γ/δ heterodimer in association with its CD3 complex, which provides transmembrane signal transduction capability (Chapter 4).¹ Specificity of the TCR for antigen resides exclusively within the highly polymorphic clonotypic ligand-binding α/β or γ/δ chains. Although many of the biochemical events leading to α/β and γ/δ T-cell activation are similar, it is important to note that there are differences between these cell types in regard to their development, their spectrum of antigen reactivity, and their role in specific immune responses. This chapter focuses on α/β T cells.

The α/β TCR specifically recognizes short peptide ligands bound to major histocompatibility complex (MHC) antigens (Chapter 5) on the surface of antigen-presenting cells (APCs) (Chapter 6). Co-receptor molecules expressed on subsets of α/β T cells determine whether the TCR recognizes class I or class II MHC. CD4 T cells are stimulated by processed exogenous antigen presented by class II MHC molecules on the surface of professional APCs. CD8 T cells respond to peptides synthesized by the presenting cells and presented by class I molecules. CD4 and CD8 associate with MHC class II and class I molecules, respectively, to stabilize the trimolecular interaction between the TCR, antigen, and MHC, which increases the effectiveness of TCR engagement.

Although the α/β -chains of the TCR contain all of the information necessary for antigen/MHC binding, these proteins cannot initiate the intracellular biochemical events that signal antigen recognition. Instead, signal transduction is accomplished by the noncovalently associated CD3 polypeptides, which include several pairs of transmembrane homodimers (Fig. 13.1) (Chapter 4). Each CD3 chain derives signaling capacity from the presence of a cytoplasmic region known as an immunoreceptor tyrosine-based activation motif (ITAM).²

CLINICAL RELEVANCE

Dysfunction or deficiency of T-cell signaling proteins (induced or spontaneous) has been causally linked to several disease states in animal or human models.

Molecules wherein mutations may lead to immune deficiency:

- >> CD45
- >> LCK
- >> ZAP-70
- >> SLP-76
- >> LAT
- >> IL-2R γ chain

Molecules wherein mutations may lead to lymphocyte hyperproliferation:

- >> CTLA-4
- >> SHP-1
- >> CD95/CD95 ligand
- >> SAP
- >> CBL/CBL-b
- >> ZAP-70

Table 13.1 Phenotypes associated with deficient function of selected T-cell signaling molecules

Molecule	Affected signaling event	Phenotype	
		Mouse	Human
TCR signaling			
CD3 γ	TCR expression	B ⁺ T ⁺ NK ⁺ SCID	B ⁺ T ⁺ NK ⁺ SCID
CD3 ε	TCR expression	B ⁺ TNK ⁺ SCID	B ⁺ T ^{+/} -NK ⁺ SCID
CD3 δ	TCR expression	B ⁺ TNK ⁺ SCID	B ⁺ TNK ⁺ SCID
CD3 ζ	TCR expression, TCR-mediated PTK activation	B ⁺ T ⁺ NK ⁺ SCID	B ⁺ T ⁺ NK ⁺ SCID
ZAP-70	TCR-mediated PTK activation	B ⁺ T ^{+/} -NK ⁺ SCID. TCR $\alpha\beta$ T cells are absent, but TCR $\gamma\delta$ T cells survive. Arthritis occurs in some inbred strains	B ⁺ T ^{+/} -NK ⁺ SCID. CD8 T-cell lymphopenia. Overexpressed in some hematologic malignancies
LCK	TCR-mediated PTK activation	B ⁺ T ^{+/} -NK ⁺ SCID. Impaired thymopoiesis and proliferation	B ⁺ T ⁺ NK ⁺ SCID. CD4 lymphopenia, absent CD28 expression on CD8 T cells, and hypogammaglobulinemia
CD45	Maintenance of SRC family PTK in “open” conformation	B ⁺ T ^{+/} -NK ⁺ SCID. Impaired thymopoiesis	B ⁺ T ^{+/} -NK ⁺ SCID. Impaired thymopoiesis, decreased cytotoxic T-cell responses, progressive hypogammaglobulinemia, genetic polymorphisms may correlate with increased prevalence of autoimmune disease
SAP	SHP-2 binding to SLAM	Increased susceptibility to lymphocytic choriomeningitis virus, reduced IgE production, NKT-cell deficiency	X-linked lymphoproliferative disease (XLP) with B-cell hyper-responsiveness, NKT-cell deficiency
WASP	Actin polymerization	Decreased T-cell proliferation and IL-2 production	Wiscott-Aldrich syndrome (immunodeficiency, atopic dermatitis, thrombocytopenia, bloody diarrhea)
CBL/CBL-b ^a	E3 ubiquitin ligase. Recruitment of CrKL/C3G inhibitory complex	Hyperproliferative T cells ^a	Proto-oncogene for leukaemia
LAT	Coupling PTK activation to downstream signals	B ⁺ T-NK ⁺ SCID. Absolute block in thymopoiesis	
SLP-76	Coupling PTK activation to downstream signals	B ⁺ T-NK ⁺ SCID. Absolute block in thymopoiesis. Defect in vascular/lymphatic development	
Itk/Rlk	Amplification of proximal PTK signals. Activation of PLC- γ 1	Defective Th2 immune responses	
CTLA-4	Inhibition of CD28-mediated co-stimulation	Fatal lymphoproliferative disease with myocarditis, pancreatitis	Allelic variants associated with autoimmunity, including Hashimoto's thyroiditis, Graves disease, and systemic lupus erythematosus
SHP-1	Downregulation of PTK activity	Autoimmunity, inflammatory lung disease. “Motheaten” mice	
IL-2R signaling			
γ c	Coupling IL-2 binding to JAK activation	B ⁺ T-NK ⁻ SCID	B ⁺ T-NK ⁻ SCID, X-linked SCID
JAK3	Phosphorylation of STAT proteins	B ⁺ T-NK ⁻ SCID	B ⁺ T-NK ⁻ SCID
^a CBL and CBL-b are closely-related; CBL-b-deficient mice develop autoimmune features and more severe lymphoproliferative disease than mice lacking CBL. γ c, common γ -chain (IL2R γ); IgE, immunoglobulin E; NK, natural killer; SCID, severe combined immunodeficiency; TCR, T-cell receptor.			

Fig. 13.1 Biochemical events in early T-cell receptor (TCR) signaling. The tyrosine phosphatase CD45 dephosphorylates the negative regulatory tyrosine residue on the CD4-associated protein tyrosine kinase (PTK) LCK, maintaining LCK in an activatable conformation (1). Engagement of the TCR α/β heterodimer and the CD4 (or CD8) co-receptors by MHC-bound peptide antigen brings activated LCK into proximity with immunoreceptor tyrosine-based activation motif (ITAM)-bearing CD3 chains. LCK phosphorylates the CD3 ζ chain within ITAMs (2). The phosphorylated ζ -chain ITAMs interact with the tandem SH2 domains of the cytoplasmic PTK ZAP-70 (3), permitting activation of ZAP-70 and phosphorylation of downstream substrates.

KEY CONCEPTS

PROTEIN TYROSINE KINASE ACTIVATION

The earliest detectable biochemical event following T-cell receptor engagement is activation of protein tyrosine kinases:

- >> Src family: LCK, FYN
- >> Syk family: ZAP-70
- >> Tec family: ITK, RLK

ACTIVATION OF PROTEIN TYROSINE KINASES BY THE TCR AND THE ROLE OF THE ITAMS

The first biochemical event known to occur following engagement of the TCR is the activation of LCK and FYN, two members of the SRC family of protein tyrosine kinases (PTKs). Similar to all SRC PTKs, LCK and FYN possess a number of features critical for their function³ (Fig. 13.2). These include an amino-terminal myristoylation sequence that directs membrane localization; a SRC homology 3 (SH3) domain that permits associations with other proteins containing regions rich in proline residues; a SRC homology 2 (SH2) domain that dictates interactions with

proteins phosphorylated on tyrosine residues; a catalytic region, and a carboxyl-terminal tyrosine residue. The precise mechanism whereby LCK and FYN are stimulated by the TCR is not clear, but both have been shown to associate physically with TCR CD3 components and/or CD4 and CD8. SRC family PTK enzymatic function is regulated in part by the state of tyrosine phosphorylation of the kinase. When the conserved carboxyl-terminal tyrosine residue is phosphorylated, the SRC family PTKs adopt a closed conformation that is the product of an intramolecular interaction between that phosphotyrosine and the SH2 domain (Fig. 13.3). This intramolecular interaction inhibits the enzymatic activity of the PTK, limiting subsequent tyrosine phosphorylation-dependent signaling events. Phosphorylation of the carboxyl-terminal tyrosine (Y505 in LCK and Y527 in FYN) is dynamically regulated.⁴ Phosphate is transferred to this residue by the cytoplasmic PTK, CSK, and removed by the transmembrane protein tyrosine phosphatase, CD45.

The phenotypes of CD45-deficient cells, mice, and humans highlight the critical regulatory importance of the carboxyl-terminal tyrosine in SRC family PTKs.⁵ TCR signal transduction in cell lines lacking CD45 is blocked at the most proximal step, and mice that have been genetically modified to lack CD45 expression exhibit profound defects in thymocyte development and subsequent T-cell activation. CD45 deficiency in humans creates a T⁺, B⁺, NK⁺ severe combined immunodeficiency (SCID) (Chapter 35). These outcomes correlate with markedly impaired LCK enzymatic activity and hyperphosphorylation on the regulatory tyrosine.

Fig. 13.2 Domain organization of T-cell receptor (TCR)-stimulated protein tyrosine kinases (PTKs). Comparative schematic representation of members of three families of PTKs required for T-cell-activating signals. In addition to catalytic domains, LCK (Src family), ITK (Tec family), and ZAP-70 (Syk family) each contain regions responsible for mediating protein–protein interactions, including SH3 and SH2 domains. SH3, Src homology 3; SH2, Src homology 2; PH, pleckstrin homology.

Following TCR engagement and PTK activation, numerous cellular substrates become tyrosine-phosphorylated, including CD3 ITAMs (Fig. 13.1). ITAM phosphorylation creates a docking site for another cytosolic PTK, zeta-associated phosphoprotein-70 (ZAP-70). ZAP-70, a member of the SYK family of PTKs, contains a catalytic domain that is located carboxyl-terminal to two tandem SH2 domains (Fig. 13.2). The ZAP-70 SH2 domains have affinity for phosphotyrosine present within ITAMs. Thus, inducible phosphorylation of CD3 γ , δ , ϵ , and ζ results in the recruitment of ZAP-70 to these components of the TCR. Upon TCR recruitment, ZAP-70 enzymatic activity is increased owing to phosphorylation by LCK, as well as autophosphorylation. The net result of these phosphorylations is conversion of the TCR from an enzymatically inactive complex to a potent PTK.

The critical importance of LCK, FYN, and ZAP-70 for both thymocyte development and mature T-cell activation has been established by studies in mutant cell lines, mice, and humans. Jurkat T cells (a human leukemic cell line commonly employed as a model for mature T-cell activation)⁶ deficient in expression of either LCK or ZAP-70 cannot be activated via the TCR. Mice deficient in ZAP-70 or LCK, but not in FYN, exhibit a significant yet incomplete block in early T-cell development. This phenotype suggests that the pre-TCR (a complex present on immature thymocytes which includes signaling components thought similar to the TCR on mature T cells) also requires SRC and SYK family PTKs to transduce signals. ZAP-70 deficiency and abnormal LCK function in humans create a T⁺B⁺NK⁺ SCID (Chapter 35).⁷

Developing and mature T lymphocytes differ in their requirements for FYN and LCK.^{8,9} Fyn deficiency has no gross effect on thymocyte development, but mice deficient in both LCK and FYN have an absolute block at the pre-TCR checkpoint. Consistent with the finding that basal TCR signals are required for naïve T-cell survival, the expression of either LCK or FYN is sufficient for survival of naïve T lymphocytes. However, mice deficient in LCK and FYN exhibit defective lymphopenia-induced homeostatic proliferation of naïve T cells. LCK but not FYN expression is able to revert this phenotype and allow this type of lymphocyte expansion.

In addition to SRC and SYK family PTKs, TCR engagement also results in the activation of a third family of cytosolic PTKs, the Tec family.¹⁰

Fig. 13.3 Model for dynamic regulation of LCK by intramolecular interaction between an SH2 domain and phosphotyrosine. The transmembrane phosphatase CD45 dephosphorylates tyrosine 505 in the carboxyl-terminus of the SRC family protein tyrosine kinase (PTK) LCK. CD45 activity maintains LCK in an “open” conformation, permitting LCK kinase domain access to intracellular substrates. CSK activity opposes that of CD45; phosphorylation of tyrosine 505 results in an intramolecular interaction between the SH2 domain and phosphotyrosine. Inhibition of LCK kinase activity correlates with the “closed” conformation (left).

KEY CONCEPTS

SIGNALING PATHWAYS

T-cell receptor engagement leads to the initiation of signaling cascades, including:

- >> PLC γ 1 activation
 - Calcium flux
 - DAG formation
- >> RAS/MAPK

Members of this family in T cells include Tec, ITK, and RLK. Tec PTKs contain SH2, SH3, and catalytic domains, as well as pleckstrin homology (PH) domains that mediate interactions with membrane-localized phospholipids (Fig. 13.2). PH domains permit the recruitment of Tec family kinases to the plasma membrane, where they can phosphorylate important substrates. Studies in mutant T-cell lines suggest that the activation of Tec family members is dependent upon the prior activation of SRC and SYK family PTKs. In addition, mice made deficient in Tec PTKs display signaling defects downstream of the TCR and chemokine receptors, as evidenced by alterations in actin reorganization, adhesion, and migration.

Unlike SRC and SYK family PTKs whose loss results in an absence of TCR signaling, Tec family kinases are thought to act as modulators of TCR signal strength. Thus, deficiency results in only partial defects in thymocyte development (both positive and negative selection), and mice lacking Tec family kinases retain peripheral T cells for functional study. Rlk and Itk are differentially expressed in the Th1 and Th2 subsets. Itk, not Rlk, is expressed in Th2 cells, for example. Deficiency of Itk results in defective interleukin-4 (IL-4) secretion and *in vivo* Th2-dependent immunity.

SECOND-MESSENGER CASCADES DOWNSTREAM OF THE TCR-STIMULATED PTKS

All of the well-established signaling pathways initiated by TCR engagement are dependent upon the activation of ZAP-70 and its association with the CD3 ITAMs. The link between PTK activation and several

Fig. 13.4 Signaling pathways activated by T-cell receptor (TCR) engagement. TCR ligation results in activation of protein tyrosine kinases (PTKs) such as LCK and ZAP-70. Phospholipase $C\gamma 1$ (PLC $\gamma 1$) becomes phosphorylated and activated by ITK and PI3K. Hydrolysis of phosphatidylinositol bisphosphate (PIP $_2$) by PLC $\gamma 1$ releases diacylglycerol (DAG) and inositol trisphosphate (IP $_3$). IP $_3$ stimulates an increase in intracellular calcium concentration, which activates the phosphatase calcineurin. Calcineurin dephosphorylates NFAT, thereby signaling NFAT translocation to the nucleus. The formation of DAG leads to activation of RAS-GRP1 GEF activity and RAS activation. Active RAS binds and stimulates the kinase RAF1, initiating a cascade of serine/threonine kinases (MAPK cascade) leading to phosphorylation and nuclear translocation of the ERK kinases. DAG formation also results in activation of the CARMA/BCL-1/MALT1 complex leading to phosphorylation of I κ B kinase (IKK). Active IKK phosphorylates I κ B- α , leading to I κ B- α degradation and release of NF- κ B to the nucleus. Transcription factors NFAT, NF κ B, and those activated by the MAPK pathway cooperate to upregulate transcription of genes such as IL-2 critical for T-cell activation.

downstream second-messenger cascades is now well established. One consequence of effective TCR stimulation is activation of the membrane-associated enzyme phospholipase $C\gamma 1$ (PLC $\gamma 1$) (Fig. 13.4).¹¹

Phosphatidylinositol 4,5-bisphosphate (PIP $_2$), a minor phospholipid constituent of the plasma membrane, serves as a substrate for PLC $\gamma 1$. PIP $_2$ hydrolysis gives rise to two biochemical second messengers, the soluble sugar inositol 1,4,5-trisphosphate (IP $_3$) and the lipid diacylglycerol (DAG). IP $_3$ binding to its cognate receptor on endoplasmic reticulum results in the release of calcium from this organelle. DAG is a physiological activator of some members of the protein kinase C (PKC) family of serine/threonine kinases. The importance of calcium mobilization and activation of PKC family members for T-cell activation was suggested by the observation that the combination of calcium ionophore and phorbol ester, pharmacologic agents which induce these biochemical events, can substitute for TCR engagement and lead to T-cell proliferation and cytokine production.¹²

Among the TCR-initiated biochemical events dependent upon calcium flux is the activation of calcineurin, a serine/threonine phosphatase. The substrates of calcineurin include members of the nuclear factor of activated T cells (NFAT) family.¹³ These transcription factors are phosphorylated in the cytosol of resting T cells. Activated calcineurin dephosphorylates NFAT, allowing it to translocate to the nucleus and bind response elements in the promoters of genes important for T-cell activation.

The importance of the calcineurin pathway in T-cell activation has been exploited clinically through the use of cyclosporine A and tacrolimus, which inhibit this pathway through distinct mechanisms. These drugs are mainstays in the prevention of human solid-organ transplant rejection (Chapter 80) and are now beginning to be used to treat autoimmune diseases such as *systemic lupus erythematosus* (Chapter 51).

The mechanistic link between TCR-induced PTK activation and the PLC $\gamma 1$ pathway remains incompletely understood. PLC $\gamma 1$ is inducibly tyrosine-phosphorylated following TCR binding, an event that correlates with increased PLC $\gamma 1$ enzymatic activity.¹⁴ However, PLC $\gamma 1$ is phosphorylated on multiple tyrosine residues, and it remains uncertain which TCR-stimulated PTK, and which tyrosine residues are most critical for PLC $\gamma 1$ activation. In fact, recent work suggests that PLC $\gamma 1$ is phosphorylated by multiple PTKs, including both ZAP-70 and members of the Tec family. Furthermore, TCR-stimulated tyrosine phosphorylation alone is not sufficient to activate PLC $\gamma 1$; localization of the enzyme probably plays a critical role as well.

A second major signaling pathway stimulated by engagement of the TCR involves activation of the small-molecular-weight guanine nucleotide-binding protein RAS.¹⁵ Evidence for the central importance of RAS activation for T-cell function has come from studies in cell lines and in genetically altered mice. Jurkat T cells expressing inhibitory

mutant forms of RAS fail to produce IL-2 following TCR engagement. In contrast, Jurkat cells expressing an activated form of RAS produce IL-2 much more readily than do wild-type cells. Similarly, mice transgenic for activating RAS mutants show alterations in thymocyte development and demonstrate a partially stimulated state in the absence of antigen binding.

RAS is a 21-kDa protein localized to the plasma membrane owing to post-translational fatty acid modifications. In its inactive state, RAS binds guanosine diphosphate (GDP). Upon RAS activation GDP is exchanged for guanosine triphosphate (GTP), allowing RAS to interact with and activate a cascade of serine-threonine protein kinases, including RAF, MEK, and the extracellular regulated kinase (ERK). This kinase cascade culminates with the nuclear translocation of ERK. Upon entry into the nucleus, ERK can phosphorylate and activate several transcription factors that are critical for TCR-induced transactivation of cytokines and other activation genes.

In T lymphocytes, exchange of GTP for GDP-bound RAS can occur through one of two distinct molecular mechanisms involving the guanine exchange factors (GEFs) SOS or RASGRP1.¹⁶ Following TCR activation, SOS is recruited to the plasma membrane through its interaction with the Grb2 adaptor protein. This mechanism is similar to events leading to RAS activation downstream of growth receptors with intrinsic tyrosine kinase activity in nonlymphoid cells. T lymphocytes express additional GEFs that are members of the Ras guanyl nucleotide-releasing protein (RasGRP) family. These proteins contain Ras exchange-, DAG binding- and EF hand-motifs. The exact mechanism of RasGRP activation remains unclear, but may involve nonclassical PKC family members such as PKC- θ or direct activation by DAG. The importance of the RasGRP pathway in TCR-mediated signaling is highlighted by the finding that deletion of RasGRP1 leads to severe defects in thymocyte development in mice. Ras activity is also regulated through the hydrolysis of RAS-bound GTP to GDP, either through the intrinsic GTPase activity of RAS or through the recruitment of GTPase-activating proteins (GAPs) to the active RAS molecule. Thus, the ability of RAS to modulate T-cell activation events is governed both by signals leading to the exchange of GTP for GDP and signals affecting the rate of GTP hydrolysis.

Stimulation of T cells also involves activation of the lipid kinase phosphatidylinositol 3'-hydroxyl kinase (PI3K) (Fig. 13.4).¹⁷ PI3K phosphorylates phosphoinositides, which play an important role in the regulation of several downstream serine/threonine kinases. The activation of PI3K requires phosphorylation of a regulatory subunit that controls catalytic activity conferred by a 110-kDa subunit. Although TCR engagement alone can stimulate some degree of PI3K function, full activity of the lipid kinase appears to require co-stimulation of the T cell through receptors such as CD28 (see below).

Cross-linking of the TCR also leads to activation and nuclear translocation of members of the nuclear factor- κ B (NF κ B) family of transcription factors (Fig. 13.4).¹⁸ Defects in immune activation result from the lack of NF κ B activity. Normally, NF κ B family members are sequestered in the cytoplasm through interaction with inhibitors of NF κ B (I κ Bs). TCR stimulation results in the formation of a multimolecular complex composed of CARMA1, BCL-10, and MALT1. Formation of this complex may involve the activation of PKC- θ . Formation of the CARMA1-BCL-10-MALT1 complex leads to activation of I κ B kinases (IKKs), phosphorylation and degradation of I κ B, and subsequent release and translocation to the nucleus of NF κ B.

■ INTEGRATION OF SECOND-MESSENGER PATHWAYS BY ADAPTOR PROTEINS ■

One of the most daunting challenges in T-cell biology is to understand how biochemical signaling pathways initiated by engagement of the TCR are coordinated to result in the appropriate biologic response. Considerable insight into how intracellular signaling pathways can be integrated has come from the recent characterization of adaptor proteins.^{14,19,20} Adaptors lack enzymatic or transcriptional regulatory activity. Instead, they possess modular domains responsible for intermolecular interactions. Both constitutive and induced intermolecular interactions mediated by adaptor molecules can provide the necessary scaffold to promote signal transduction events.

Adaptor proteins commonly contain modular domains that exhibit affinity for phosphorylated tyrosine residues (Fig. 13.5A). Such regions include the SH2 and phosphotyrosine-binding (PTB) domains. Each of these domains recognizes phosphorylated tyrosine residues within a specific sequence context. For example, PTB domains obtain their specificity based on residues amino-terminal to the phosphotyrosine, whereas SH2 domains recognize particular sequence motifs carboxyl-terminal to the key phosphotyrosine. Other adaptor domains include SH3 modules, which bind proline-rich regions; WW regions responsible for interactions with proline/tyrosine or proline/leucine motifs; and PH domains that have specificity for phospholipids.

It is clear that many ubiquitously expressed adaptors, as well as others with more restricted tissue distribution, function in diverse cellular processes. Several hematopoietic-specific adaptors are now known to play essential roles in T-cell development, in coordinating the signals necessary for mature T-cell activation, and in the process of terminating T-cell responses. Two adaptors critical for T-cell activation, linker of activated T cells (LAT) and SH2 domain containing leukocyte phosphoprotein of 76 kDa (SLP-76), are described in this section.

Both LAT and SLP-76 were identified in efforts to characterize substrates of the PTKs stimulated by TCR engagement. LAT is a 36-kDa integral membrane protein that contains numerous tyrosine residues within its cytoplasmic tail (Fig. 13.5A). The tyrosines exist within the correct sequence motifs needed to bind the SH2 domains of other T-cell signaling molecules. In stimulated T cells LAT becomes associated with Grb2, GADS (another Grb2 family member), PLC γ 1, and the p85 subunit of PI3K. It is likely that these induced intermolecular interactions are critical for communicating TCR engagement to downstream second-messenger cascades. The importance of LAT for T-cell activation was suggested by the signaling phenotype of LAT-deficient variants of the Jurkat T-cell leukemic line. Engagement of the TCR on these cells fails to result in signaling events downstream of ZAP-70 activation. Furthermore, examination of LAT-deficient mice revealed an essential role for LAT in T-cell development. The Lat^{-/-} mice have significantly decreased numbers of thymocytes, which are arrested at an early stage during development. Arrested thymocyte development leads to the complete lack of T cells in Lat^{-/-} peripheral lymphoid organs. In recent *in vivo* studies, a knockin of a PLC γ 1-binding mutant of LAT partially restored thymocyte development but also resulted in a lymphoproliferative phenotype in adult animals.

Using similar approaches, it was shown that SLP-76 is absolutely required for both T-cell development and signaling via the mature TCR.

Fig. 13.5 Model for adaptor protein-mediated coupling of the T-cell receptor (TCR) to phospholipase $C\gamma_1$ ($PLC\gamma_1$) activation. (A) Structural schematics of three adaptors implicated in plasma membrane proximal biochemical events. SH3 domains mediate association with proline-rich regions; SH2 domains associate with phosphorylated tyrosine residues. (B) LAT and SLP-76 are among the substrates of the TCR-activated protein tyrosine kinases (PTKs). When tyrosine residues within the LAT cytoplasmic tail are phosphorylated, GADS binds to LAT through the GADS SH2 domain. Recruitment of GADS results in relocalization of SLP-76, as the proline-rich region of SLP-76 mediates constitutive association with the SH3 domain of GADS. Tyrosine-phosphorylated SLP-76, in turn, becomes associated with ITK via the ITK SH2 domain. ITK is thus brought into proximity with membrane-localized substrates, including $PLC\gamma_1$. Activation of $PLC\gamma_1$ leads to hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP₂) and activation of transcription factors such as nuclear factor- κ B (NF κ B), activating protein 1 (AP-1), and nuclear factor of activated T cells (NFAT). SH2 domain containing leukocyte phosphoprotein of 76 kDa (SLP-76) also recruits several other signaling molecules, such as VAV, NCK, HPK1, and ADAP, thereby regulating changes in the actin cytoskeleton and adhesion. Phosphorylation of linker of activated T cells (LAT) also leads to recruitment of Grb2/SOS and an additional pathway for RAS activation. TM, transmembrane domain; P-Y, sites for phosphorylation of tyrosine; pro-rich, proline-rich regions.

Thus, mice deficient in SLP-76 show a complete block in thymocyte development. In mutant T-cell lines lacking SLP-76, the $PLC\gamma_1$ and RAS/MAPK signaling cascades are not activated by TCR ligation, despite normal TCR-stimulated activation of ZAP-70. SLP-76 contains an amino-terminal region with tyrosine phosphorylation sites, a central proline-rich domain, and a carboxyl-terminal SH2 domain. Unlike LAT, SLP-76 does not possess a transmembrane domain. By means of its proline-rich region, SLP-76 constitutively associates with GADS and through its SH2 domain can inducibly interact with other tyrosine-phosphorylated adaptors such as HPK-1 and ADAP. Following tyrosine

phosphorylation, SLP-76 inducibly binds other SH2-domain-containing proteins (e.g., VAV, an exchange factor for the RAC GTP-binding protein; NCK, an adaptor protein; and ITK, a Tec family PTK). Each of the SLP-76 domains appears critical for its function, as the overexpression of mutant variants of SLP-76 is unable to restore TCR signaling efficiency fully in either Jurkat T cells or SLP-76-deficient mice. In contrast, overexpression of wild-type SLP-76 dramatically augments TCR-stimulated second-messenger production.

One model of how SLP-76 and LAT functionally interact is as follows.²¹ Following TCR engagement, the two adaptors associate with

each other, bridged by GADS and perhaps PLC γ 1. These interactions anchor a multimolecular “signalosome” at the plasma membrane (Fig. 13.5B). Formation of this complex brings Itk into proximity of PLC γ 1, resulting in phosphorylation and activation and leading to the generation of IP₃ and DAG, as described above.

Along with LAT and SLP-76, T cells express a large number of other adaptor proteins that appear to play important roles in promoting TCR-mediated signal transduction events. Many of these are widely expressed, and some are expressed only in hematopoietic cells. Adaptors are important for the coordination of both positive and negative aspects of TCR activation. For example, in the absence of antigen, the transmembrane adaptor PAG binds to the PTK CSK, bringing it to the plasma membrane.¹⁹ Membrane-localized CSK phosphorylates the regulatory tyrosine of LCK, thus keeping LCK inactive. Delineating the positive and negative aspects of signal transduction mediated by subcellular localization of kinases and phosphatases is an ongoing area of active research by multiple laboratories worldwide.

CO-RECEPTORS TRANSDUCE SIGNALS THAT ARE INTEGRATED WITH TCR SIGNALS

Engagement of the TCR without the concomitant stimulation of other signaling pathways does not lead to full T-cell activation. T-cell proliferation and the initiation of effector function require that the T cell must receive additional signals via other cell surface receptors.²² This requirement for multiple signals allows the T cell to express an exquisitely sensitive TCR while protecting against the inappropriate activation of potentially dangerous effector cells. Because T cells respond to antigens presented on APCs, stimulation under physiological conditions involves the potential engagement of multiple ligand co-receptors on the T cell by various ligands on the APC. Many of these co-receptors have been characterized, and progress has been made in our understanding of how these molecules promote T-cell activation. One obvious way in which co-receptors may function is to increase the avidity of the interaction between the T cell and the APC. Interestingly, however, many co-receptors are also capable of transducing signals themselves, some independent of and others synergistic with the TCR. Additionally, co-receptors are often important as recruiters of the cytoplasmic signaling molecules and the adaptor proteins described above.

The most intensively studied co-receptors are CD4 and CD8 (Chapter 4). CD4 and CD8 expression defines subsets of T cells responding to class II or class I-bound peptide antigen, respectively (Chapter 9). In addition to increasing the affinity of the TCR–antigen interaction, both CD4 and CD8 participate in TCR-mediated signal transduction, because they each associate with LCK.² This constitutive interaction, which occurs via specific residues within the CD4 and CD8 cytoplasmic domains, localizes a key effector enzyme to the TCR complex.

CO-STIMULATORY MOLECULES ARE REQUIRED FOR OPTIMAL T-CELL ACTIVATION

As stated earlier, T-cell stimulation is a composite of TCR cross-linking and co-stimulatory signals. In contrast to the CD4 and CD8 co-receptors that bind to MHC molecules, other ligands on APCs interact with additional T-cell surface proteins termed co-stimulatory molecules. The importance of co-stimulatory molecules is implied by the large number

of proteins expressed on the cell surface of T cells and the number of ligands expressed on APCs. Initially, it was thought that there is redundancy in co-stimulation; in other words, as long as a co-stimulatory signal is sufficient to attain an activation threshold, it does not matter which specific molecules are involved. However, recent advances in the understanding of the molecular mechanisms of co-stimulation indicate that different co-stimulatory receptor–ligand pairs confer different phenotypic responses.

The best-characterized co-stimulatory molecule present on T cells is CD28,^{23, 24} a constitutively expressed homodimeric transmembrane glycoprotein. CD28 binds to two ligands expressed on APCs, B7.1 (CD80) and B7.2 (CD86). Ligation of CD28 on its own has little effect on T-cell activation; however, when CD28 is engaged along with the TCR, many TCR signals are augmented. Indeed, concomitant CD28 and TCR engagement is required for activation of naïve T cells. Co-stimulation of the TCR plus CD28 dramatically augments IL-2 production, both by increasing transcription of the IL-2 gene and by stabilizing its mRNA. If the TCR is engaged in the absence of CD28 co-stimulation, such a stimulus leads not to activation but either to T-cell death by apoptosis or to a state of unresponsiveness.

Although much has been learned about the signal transduction events mediated by CD28, which of these biochemical events is critical for the biologic effects of CD28 remains unclear.²⁴ CD28 contains no intrinsic enzymatic activity, but it is inducibly phosphorylated on tyrosine residues during T-cell activation. These phosphorylated tyrosines recruit several signal-transducing molecules possessing SH2 domains, including the 85-kDa subunit of PI3K, Grb2, and ITK. Several lines of evidence suggest that TCR- and CD28-dependent activation of PI3K interferes with, rather than stimulates, IL-2 gene transcription. CD28 engagement also co-stimulates activation of members of the mitogen-activated protein kinase (MAPK) family, in particular c-JUN N-terminal kinase (JNK). CD28-stimulated JNK activity plays an important role in optimizing cytokine production and protecting T cells from apoptosis. Another postulated mechanism for how CD28 promotes T-cell activation rests on the observation that stimulation of the TCR alone results in activation of RAP1, a small-molecular-weight GTP-binding protein. Activated RAP1 competes with RAS for downstream effectors and prevents the propagation of RAS-mediated signaling events. Co-stimulation of T cells via the TCR plus CD28 interferes with RAP1 activation, allowing the RAS pathways to signal effectively.

CD28 is the prototype member of a family of structurally related co-stimulatory receptors. CD28 binds to B71 (CD80) and B72 (CD86) expressed on APCs.²³ Other family members include CTLA-4 (cytotoxic lymphocyte-associated antigen 4), ICOS (inducible co-stimulator), PD-1 (programmed death 1), and BTLA (B- and T-lymphocyte attenuator). Cellular expression patterns and functional consequences vary drastically for molecules in this group. While CD28–B7 interactions are co-stimulatory, ligation of CTLA-4 by B7 is inhibitory (see T-cell anergy section below). As its name implies, ICOS is not expressed on naïve cells but is induced following stimulation. ICOS–ICOS-L interactions are important for T-cell help to B cells. Blockade of this interaction can affect the immune response in murine models of autoimmunity such as collagen-induced arthritis and experimental autoimmune encephalomyelitis (EAE), and CD28–B7 binding is thus a potential therapeutic target in solid-organ transplants. ICOS deficiency can also lead to common variable immune deficiency (CVID) (Chapter 34). PD-1 can interact with two different ligands, PDL-1 and PDL-2. PD-1–PDL-1/PDL-2 interaction can lead

KEY CONCEPTS

to co-stimulation or to downregulation of the immune response depending on their cellular context and the experimental system utilized.

A second large class of co-stimulatory molecules includes members of the tumor necrosis factor receptor (TNFR) family.²⁵ Co-stimulatory TNFR family members include OX40 (CD134), 4-1BB (CD137), HVEM, CD30, and GITR. These are type I transmembrane proteins containing extracellular cysteine-rich domains. The cytoplasmic domains contain sequences that recruit a family of adaptor molecules known as TNF receptor-associated factors (TRAFs). For example, trimerization of OX40 leads to recruitment of TRAF2, TRAF3, and TRAF5, while GITR recruits TRAF1, TRAF2, and TRAF3. The induced downstream effector pathways also vary between the TNFRs, but NF κ B induction is common among them. A substantial amount of data has been gathered regarding the cellular expression and function of each of these receptors and details of each receptor to T-cell activation, and the immune response are beyond the scope of this chapter. OX40 is preferentially expressed on activated CD4 T cells with its expression peaking approximately 48 hours after CD3/CD28 stimulation. OX40 deficiency leads to defects in CD4 T-cell proliferation and can affect survival of memory T cells. Blockade of the OX40–OX40L interaction is required for the induction of EAE and collagen-induced arthritis. *In vitro*, the engagement of OX40 enhances the proliferative response of T cells to submitogenic anti-TCR stimuli. Further, OX40 blockade partially interferes with this T-cell response. Little is yet known about the mechanism of OX40 action.

Like OX40, 4-1BB is a co-stimulatory molecule present primarily on activated T cells. Although it is expressed on both CD4 and CD8 cells, some data suggest that the engagement of 4-1BB preferentially leads to CD8 cell proliferation and protection from apoptosis. The delayed kinetics of 4-1BB expression suggest that, in contrast to the early-acting CD28, 4-1BB plays a role later in the immune response.

TOLERANCE

Tolerance is an inherent property of the immune system that governs the ability to respond against foreign antigens (nonself) without attacking the host (self). A lack of self-tolerance leads to autoimmune disease, whereas a host displaying excessive tolerance may be more susceptible to pathogens. The immune system in any individual must therefore be able to distinguish subtle differences between self and nonself. To accomplish this delicate task, multiple complementary mechanisms of immune system tolerance have developed. The remainder of this chapter will discuss tolerance in the T-cell compartment.

The concept of immune tolerance pre-dated our understanding of the cellular and molecular bases for the phenomenon. Owen's experiments in cattle showed that a shared blood supply during development led to lifelong immune tolerance. Billingham, Brent, and Medawar expanded upon the experiments in 1953 by showing that *in utero* inoculation with foreign tissue resulted in tolerance to foreign skin grafts later in life.

The process of tolerance is often divided between central and peripheral mechanisms. Central tolerance refers to tolerance that is induced during development of T cells in the thymus (Chapter 9). Central tolerance occurs in an antigen-specific fashion through the process of clonal deletion. Gene rearrangement to form the TCR is a random process that allows for the generation of T cells with an incredible repertoire of specificities (Chapter 4). Invariably, some of these receptors will react against self-protein products. It is believed that lymphocytes specific for MHC plus self-peptides will encounter most of these self-antigens during development in the thymus. In contrast to mature T cells that respond to encounter with their specific antigen with a program of proliferation and differentiation, immature lymphocytes respond by undergoing a process of activation-induced cell death. Although there are mechanisms (see below) to ensure a full repertoire of self is expressed in the thymus, it is invariable that some self-reactive cells will develop and emigrate from the thymus to the peripheral lymphoid compartment. Control of such 'escaped' autoreactive cells is achieved through peripheral tolerance mechanisms.

CENTRAL TOLERANCE/CLONAL DELETION

While the concept of T-cell tolerance is decades old, it took the development of new techniques and reagents to track the fate of clonal T-cell populations before the molecular mechanisms of clonal deletion could be elucidated.^{26–28} Single-cell identification using monoclonal antibody recognizing the V β 17 TCR variable region demonstrated clonal deletion of developing T cells that express MHC I-E. CD4⁺CD8⁺ (double-positive (DP)) thymocytes expressing V β 17 were present, but CD4 single-positive (CD4SP) or CD8SP were not. This suggested that clonal deletion occurs at the DP to SP transition. Further studies in this model system eventually showed deletion was specific not only for the expression of I-E, but also required expression of an endogenous murine retrovirus, which appeared to serve as the dominant self-antigen.

The next significant advance in our understanding of central tolerance made use of new technologies to manipulate the mouse genome by producing transgenic mice expressing a single specificity TCR. The vast majority of developing T cells in H-Y mice, the first TCR-transgenic model of clonal deletion, are reactive against a Y-chromosome-encoded antigen, H-Y. Massive deletion of these cells results in small thymi in male mice with only a small number of DP thymocytes able to survive the antigen-induced cell death. Since these initial descriptions, significant advances have been made. Depending on the experimental system employed, deletion can occur prior to, during, or after the double-positive stage.

Deletion for self-reactivity implies that the extent of autoreactivity of the developing thymocytes is systematically calibrated. A currently favored model is one that employs strength of signal as determined by a combination of TCR affinity and co-stimulation to assess the extent of self-reactivity. Signals that go beyond a threshold of acceptability lead to clonal deletion. This model is supported by experiments in which the TCR signaling machinery has been genetically altered to increase or decrease signal intensity from each TCR. For example, an increase in the

number of ITAMs (presumably leading to increases in downstream signals) enhances clonal deletion in a transgenic system.²⁹ Similarly, transgenic alterations of the levels of CD8, a positive regulator, or CD5, the negative regulator,³⁰ also affect the efficiency of clonal deletion.

An implicit assumption required for clonal deletion to be a major mechanism of tolerance is that T cells must come into contact with all self-antigens during thymocyte maturation. It is easy to recognize how deletion of cells reactive to MHC and other widely expressed protein products can occur in the thymus. However, there are also self-antigens whose expression is restricted to a specific tissue or developmental time-point. What are the mechanisms that allow clonal deletion to antigens expressed only in the pancreas or testes, for example? One possibility is that all proteins could be transported to the thymus by APCs. Another model holds that subsets of thymus-resident APCs may “ectopically” express tissue-specific antigens. Recent work describing the function of the transcription factor AIRE supports the latter model.³¹

AIRE expression drives medullary thymic epithelial cells (mTECs) to express peptides from open reading frames ectopically. Self-reactive developing T cells are thus exposed to tissue-specific self-peptides in the thymus and are deleted. AIRE-deficient humans and mice develop autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APS-1 or APECED in humans: Chapter 35), emphasizing the role of central tolerance in preventing T-cell-mediated autoimmune disease.

PERIPHERAL MECHANISMS OF TOLERANCE

Clonal deletion, like all biological processes, is not perfect. Given the potential for autoimmune destruction should clonal deletion fail (as typified in those individuals with an AIRE mutation), there must be backup mechanisms to control autoreactivity for those few cells that manage to escape the thymus. These mechanisms include immune privilege, anergy, and regulation.

Immune Privilege

The concept of ‘immune privilege’ was first described by Medawar more than 50 years ago. Typically described areas of immune privilege include the anterior chamber of the eye, the brain, and the fetus in pregnant females.³² Both the eye and the brain have a limited capacity for regeneration, and it is believed that an immune response in these areas could have devastating effects on the individual. As a fetus expresses MHC derived from both parents, peripheral tolerance of the mother to the fetus is required for fetal survival.

Multiple mechanisms have been proposed to account for immune privilege. Medawar believed that tolerance in these areas was due to limited lymphatic drainage. In this model, lymphocytes cannot easily gain entrance to the privileged site and foreign antigens deposited there are not transported to secondary lymphoid organs, which prevents initiation of an immune response. One additional local mechanism that likely contributes to tolerance at these locations is a low level or complete absence of expression of classical MHC class Ia protein on cells of the eye and brain. Low level expression of MHC molecules may be required to protect some of these cells from CTL-mediated cell lysis (Chapters 5 and 18). In the case of the developing fetus, the cells of the villous trophoblast lack expression of class I MHC.

Cells in these areas also express cell surface and soluble factors that downregulate the immune response. For example, ocular cells express

pro-apoptotic cell surface molecules such as Fas ligand (FasL) and TRAIL (Chapter 14). These TNF family members may contribute to apoptosis of infiltrating T and other inflammatory cells bearing ‘death receptors.’ In mice, the presence of FasL on ocular cells is critical in the acceptance of corneal allografts. Cytokines produced at sites of immune privilege are also likely to contribute to the inhibition of inflammation (Chapter 10). The presence of high levels of the anti-inflammatory cytokines TNF- β and migration inhibitory factor (MIF) leads to inhibition of NK cell-mediated cytolytic activity.

T-cell anergy

Cellular proliferation and/or potentiation of T-cell effector function are not inevitable consequences of TCR engagement. In fact, under some conditions TCR ligation results in a state of T-cell unresponsiveness to subsequent TCR engagement.^{33, 34} Known as T-cell anergy, this state appears to result either when the TCR is engaged without concomitant co-stimulation, or when the ligand for the TCR is not of sufficient affinity to initiate the full spectrum of biochemical second messengers. This phenomenon was first noted by stimulating T cells in the presence of metabolically inactivated APCs. Subsequently, it was shown that CD28 co-stimulation could prevent the induction of anergy. Anergic cells are unable to proliferate or secrete cytokines upon TCR-mediated restimulation. Interestingly, supplementation of cultures with IL-2 can overcome the anergic state *in vitro*.

Several novel reagents and unique experimental systems have recently provided insights into how TCR signaling events can lead to either anergy or full T-cell activation. Mice made transgenic for specific TCR complexes have proved to be useful models for studying differential responses to TCR engagement *in vivo* and *in vitro*. TCR-transgenic mice produce T-cell repertoires largely restricted to a single specificity. T cells from such mice respond fully when presented with a specified peptide antigen, but exhibit an anergic response when that peptide is subtly altered. Opposing biologic responses of TCR-transgenic T cells isolated from these mice correlate with differences in biochemical events downstream of TCR ligation. Specifically, NFAT activity without concomitant increases in activating protein 1 (AP-1) transcription factor activity leads to anergy (Fig. 13.6A). Relatively unopposed NFAT activity can be induced experimentally either by treatment with calcium ionophore or stimulation through the TCR while blocking CD28 co-stimulation with the CLTA4-Ig recombinant protein.

Biochemical analysis of experimentally anergized T cells has shown alterations in signal transduction downstream of the TCR in the induction of anergy. For example, delivery of an anergic stimulus to T cells results in phosphorylation of the TCR ζ chain at sites that differ from those phosphorylated when the TCR is stimulated with a full agonistic peptide.^{35, 36} It is not yet clear how ligand binding is translated into differential ζ phosphorylation, but the downstream consequences of this alteration in proximal signaling appear to be profound.

Additional differences in TCR-mediated biochemical events have been documented in previously anergized versus fully activated T cells. One model for the generation of anergy involves the adaptor protein CBL.³⁷ FYN kinase activity is increased and this src family kinase can be found associated with the CBL adaptor protein in anergized cells. CBL becomes phosphorylated on tyrosines following TCR engagement, and then associates with CRKL, another adaptor protein (Fig. 13.6B). CRKL, in turn, binds to C3G, which is a guanine nucleotide exchange

Fig. 13.6 An *in vitro* model for anergy induction. (A) Stimulation of T cells by cross-linking of both T-cell receptor (TCR)/CD3 and CD28 lead to upregulation of both the nuclear factor of activated T cells (NFAT) and activating protein 1 (AP-1) transcription factors, leading to increased transcription of the interleukin-2 (IL-2) gene and activation. An imbalance of activated NFAT and AP-1 by blockade of CD28 signals (middle) or calcium ionophore (right panel) leads to an anergic phenotype. (B) A model for anergy maintenance involving Cbl. When a partial agonist or antagonist signal is delivered to the TCR, c-CBL becomes tyrosine-phosphorylated. Phosphorylated CBL acts as a scaffold for the assembly of a complex consisting of adaptor proteins CRKL and C3G. C3G is thus positioned to perform GTP/GDP exchange for the small-molecular-weight G protein RAP1, which sequesters the RAF kinase away from the activating RAS/MAPK kinase cascade (right half of schematic).

factor for the small-molecular-weight GTP-binding protein RAP1. Formation of the ternary complex involving CBL, CRKL, and C3G results in recruitment of C3G to a position where it can activate RAP1. GTP-bound RAP1 effectively interferes with signaling molecules downstream of RAS by sequestering RAS-stimulated effector proteins. Furthermore, differential activation of members of the MAPK family has been observed. Consistent with this model, the Cbl-b, Itch, and GRAIL E3 ligases are upregulated in calcium ionophore-induced anergy and result in decreased levels of PLC γ 1, PKC- θ , and RAS GRP. A complementary model centers around the LAT adaptor molecule.³⁸ As described above, LAT is normally palmitoylated and its membrane localization

restricted to detergent-insoluble lipid rafts. In previously anergized T cells, however, LAT palmitoylation and phosphorylation are both decreased. This defect is not due to alterations in either CD3 ζ and ZAP-70 phosphorylation, nor is it directly related to Cbl-b.

Regulation

The past 10 years have seen the re-emergence of the concept of active immune regulation as a process that leads to tolerance. So-called regulatory T cells or Tregs can actively suppress the immune system (Chapter 16).^{39, 40} Functional and phenotypic characterization of these

KEY CONCEPTS

IMMUNOSUPPRESSIVE DRUGS THAT AFFECT T-CELL SIGNALING

Cyclosporine/tacrolimus inhibits T-cell receptor (TCR)-generated signals

Anti-TCR antibodies block TCR signals

CTLA-4Ig blocks CD28 signals

Rapamycin inhibits interleukin-2 (IL-2)-generated signals

cells led to the revelation that Tregs are capable of inhibiting the proliferation of and cytokine production by naïve and memory T cells through a cell contact-dependent mechanism. By regulating the activation and proliferation of antigen-specific effectors, Tregs promote tolerance to self and suppress autoimmunity *in vivo*.

Identification of Treg cells was initially described based on co-expression of CD4 and CD25, but there is no single cell surface marker that is entirely specific for Tregs. CD25, for example, is found not only on Tregs, but also on activated T cells. In general, Tregs express GITR, CD103, CTLA-4, lymphocyte activation gene 3 (LAG-3), and low levels of CD45RB. More recently, expression of the transcription factor Foxp3 has been shown to correlate tightly with regulatory capacity in both humans and mice. The absence of Foxp3 either through spontaneous mutation (the scurfy mouse) or through targeted disruption of the gene leads to the absence of T cells with regulatory activity. Conversely, overexpression of Foxp3 by transgenesis or retroviral methods leads to an excess of T cells with regulatory activity.

Mice lacking Foxp3 exhibit autoimmune disease in multiple organs. In humans, mutations in Foxp3 account for a majority of cases of immune dysfunction/polyendocrinopathy/enteropathy/X-linked (IPEX) syndrome. The signs and symptoms of Foxp3-deficient disease are similar in mice and humans. Affected human males develop an autoimmune syndrome consisting of lymphoproliferation, thyroiditis, insulin-dependent diabetes mellitus, enteropathy, and other immune disorders.

Multiple research groups have taken advantage of using Foxp3 as a marker for regulatory T cells by generating gene-targeted mice in which a fluorescent protein has been knocked-in to the *FoxP3* locus. In these mice, cells that express FoxP3 can be identified and isolated based on fluorescence. Such reporter mice have been used to confirm that most, but not all, CD4⁺FoxP3⁺ cells are CD25⁺ and that most have regulatory activity. Whether Foxp3 expression is required for maintenance of Treg function or only for commitment to the Treg lineage remains an open question.

Programmed cell death in lymphocytes

14

Helen C. Su, João Bosco Oliveira, Michael J. Lenardo

Normal immune cell homeostasis reflects a dynamic balance between cell proliferation and cell death.¹ Lymphocyte clones bearing uniquely rearranged antigen receptors have been estimated at a frequency of between one in 10^{18} to one in 10^{11} in immunologically naïve humans.² During the first week after an immune response to pathogen, antigen-specific lymphocyte cell numbers will increase 100- to 5000-fold. However, cell numbers decline once the infection has resolved, with up to a 20-fold decrease in the first month. This contraction phase is critical to the maintenance of homeostasis, because immunological space is limited.

Cells that escape death during the contraction phase become memory cells poised to fight future encounters with the same pathogen. During an encounter with a new antigen, a clone of specific reactivity must compete with other lymphocytes for access to the antigen on antigen-presenting cells (APC), as well as co-stimulatory signals and cytokines. Thus, the presence of previously expanded but noncontracted lymphocytes could potentially hinder the development of an efficient immune response to a new antigen. An excess of senescent, damaged, or autoreactive cells could also predispose to autoimmunity or neoplasia. These considerations provide the rationale for the existence of programmed cell death mechanisms in lymphocytes, which serve to counterbalance cell division and growth.

Mechanisms of programmed cell death are highly conserved between species, with homologues of mammalian death genes found in nematodes. These genetic programs contribute to the proper development of nonimmune organ systems as well.³ Studies of mice genetically deficient in certain key cell death proteins have shown that these mechanisms contribute to development of the mammalian nervous and reproductive systems and can be activated in nonimmune cells such as hepatocytes.⁴ Investigations of humans have established that programmed cell death mechanisms are physiologically important both during lymphocyte development and in proper homeostasis of mature peripheral T and B lymphocytes.⁵ This chapter focuses on our current understanding of programmed cell death mechanisms in mature lymphocytes, as revealed by studies in humans having rare genetic disorders. For further details, we refer readers to several recent reviews.^{6–8}

■ FORMS OF PROGRAMMED CELL DEATH ■

The best-studied form of programmed cell death is apoptosis, a term coined in 1972 by Kerr and colleagues, which literally means ‘falling leaves.’⁹ However, Virchow described this phenomenon as early as 1859. Apoptotic cells exhibit a morphology characterized by cell shrinkage and rounding, vacuolar and vesicular formation, nuclear condensation with fragmentation, membrane blebbing, and breakdown of cells into apoptotic bodies containing nuclear fragments and intact organelles (Fig. 14.1).¹⁰ *In vivo*, apoptotic bodies are rapidly engulfed by phagocytes and do not elicit an inflammatory response. Biochemically, these changes result from a highly regulated series of molecular events, which we describe later.

Apoptosis can be distinguished from a different form of cell death called necrosis. Necrosis is characterized by cell swelling, an apparent disorganized breakdown of organelles, and plasma membrane rupture and leakage. Necrosis induces a local inflammatory reaction (Fig. 14.1).¹⁰ It can be induced by many stimuli, such as hypoxia, mechanical damage, and chemicals.

Apoptotic cells can also undergo secondary necrosis, especially when death outpaces phagocytosis. Although usually thought to be an ‘accidental’ form of death, necrosis can be a form of programmed cell death initiated when apoptosis is blocked.⁵ As more becomes known about programmed necrosis and other forms of alternative cell death, it is likely that humans with disease resulting from abnormalities in these pathways will be discovered. Here we focus on apoptosis, which is the best-understood form of programmed cell death in the immune system.

■ APOPTOSIS SIGNALING PATHWAYS ■

Basic components of a conserved signaling pathway for apoptosis were first identified genetically in the nematode *Caenorhabditis elegans*. This discovery was recognized by the 2002 Nobel Prize in Physiology or

Fig. 14.1 Transmission electron micrographs showing morphologic features of dying Jurkat T cells. (A) A normal cell is shown for comparison. The apoptotic cell in (B) is shrunken and displays chromatin condensation (asterisk at electron-dense crescent) and many apoptotic bodies (arrows). Membrane blebbing is not seen in this image. The necrotic cell in (C) is swollen and displays numerous disintegrated organelles and disruption of its plasma membrane (arrows). The chromatin condensation (asterisk) is consistent with secondary necrosis occurring during late apoptosis. (Courtesy of Dr. Lixin Zheng, NIAID, NIH.)

Medicine, which was awarded to Brenner, Horvitz, and Sulston.³ During *C. elegans* development, 131 of the 1090 cells generated disappear in the adult animal. Several key genes – *ced-3*, *ced-4*, *ced-9*, and *egl-1* – control the death of these cells. Remarkably, these genes have mammalian homologues, which are caspases, APAF-1, B-cell lymphoma 2 (BCL-2), and BH3-only proteins of the BCL-2 family, respectively. The proteins link to form a signaling pathway in which CED-3 kills, CED-4 promotes CED-3 killing, CED-9 blocks CED-4, and EGL-1 in turn blocks CED-9. The relationships between these death functions are much the same in mammals, including humans.

The outcome – apoptosis – hinges critically upon its last step, activation of caspases. These key enzymes are cysteinyl proteases that cleave after specific aspartyl residues. Although certain caspases participate in proinflammatory cytokine maturation, the rest participate in apoptosis induction. Caspases exist in the cytoplasm as inactive zymogens, so the key to their regulation is proteolytic processing and rearrangement of their conformation into a highly active form. Various stimuli can trigger the formation of signaling platforms anchored by either mitochondria-derived proteins or death receptors (discussed below). Oligomerization into these stoichiometric activation complexes activates initiator caspases, which in turn cleave and activate effector caspases.

KEY CONCEPTS

APOPTOSIS

- >> Programmed cell death is a normal physiologic process of mature peripheral lymphocytes:
The best-characterized form of programmed cell death is apoptosis
- >> The signaling pathway for apoptosis is conserved among worms, mice, and humans
- >> Apoptosis can proceed through an extrinsic pathway involving death receptors, or an intrinsic pathway involving mitochondria (Fig. 14.2):
Both pathways activate caspases in an intracellular enzymatic cascade that leads to the morphological features of cell death
- >> Actively cycling lymphocytes are most susceptible to death:
Excess antigen can induce apoptosis via death receptors
Limited antigen levels can lead to cytokine withdrawal, which in turn can induce apoptosis
- >> Lymphocyte and dendritic cell apoptosis serves to maintain tolerance and prevent autoimmunity

Effector caspases cleave substrates such as poly(ADP-ribose) polymerase (PARP), inhibitor of caspase-activated DNase (ICAD/DFF45), Rho-associated coil-coil-forming kinase I (ROCK I), nuclear lamins, actin, fodrin, and keratin. These proteins function to repair DNA, maintain the integrity of plasma membrane and subcellular organelle compartments, and make up nuclear and cytoskeletal architecture. Proteolysis of these substrates presumably leads to the morphologic changes seen in apoptosis, which culminates in cell death.

In mammals, two principal pathways initiate apoptosis (Fig. 14.2). The core signaling pathway elucidated in nematodes corresponds more closely to the intrinsic (mitochondrial) pathway. By contrast, the extrinsic (death receptor) pathway proceeds separately and is not found in simple invertebrates. Both intrinsic and extrinsic pathways converge at the step of caspase activation. The precisely ordered sequence of molecular events that comprise these pathways is discussed below.

INTRINSIC (MITOCHONDRIAL) PATHWAY

Many physiologically important stimuli trigger the intrinsic pathway of apoptosis. These include negative selection of T cells during thymic education, growth factor or cytokine deprivation, DNA damage, and treatment with cytotoxic drugs such as chemotherapeutic agents. Proteins of the BCL-2 family control the intrinsic pathway.^{7, 11} The fine balance between the levels and activation status of the pro- and anti-apoptotic members of this family determines the cell's fate. Structurally, all members of the BCL-2 family share one or more of the four known BCL-2 homology regions (BH). The pro-survival members share three or four BH regions and include BCL-2, BCL-X_L, A1/BFL-1, BCL-w, BOO/DIVA/BCL-B, and MCL-1. The pro-apoptotic members, which have two or three BH regions, structurally resemble their pro-survival relatives, and include BAX, BAK, BOK/MTD, Bcl-X_S, and Bcl-G_L. Finally,

a subgroup of pro-apoptotic members, named "BH3-only" proteins, contain only one BH region. This subgroup includes BAD, BID, BIM, BIK/NBK, BLK, HRK/DP5, Bcl-G_S, BMF, NOXA, and PUMA/BBC3.

Although certain details of how these proteins control the intrinsic apoptosis pathway remain unclear, we summarize here the most accepted current model (Fig. 14.2). The BH3-only proteins seem to act as sensors for different apoptotic stimuli. For example, BIM serves as a sensor for growth factor withdrawal, and PUMA for DNA damage. Activated BH3-only proteins induce translocation of the pro-apoptotic protein BAX from the cytosol to the mitochondria, where it clusters with BAK. This leads to pore formation in the outer mitochondrial membrane, loss of inner mitochondrial transmembrane potential, and release of several apoptotic proteins such as SMAC/DIABLO, apoptosis-inducing factor (AIF), and cytochrome c. Released cytochrome c oligomerizes in the cytosol with APAF-1 and procaspase-9 to form, in the presence of Ca²⁺ and ATP, a caspase-9-activating complex called the apoptosome. Once activated within this complex, the initiator caspase-9 cleaves and activates downstream effector caspases such as caspase-3. The resulting caspase cascade leads to cell death. Anti-apoptotic BCL-2 members may promote survival by sequestering and inactivating BH3-only proteins or other pro-apoptotic proteins, thereby preserving mitochondrial integrity and cell survival.

EXTRINSIC (DEATH RECEPTOR) PATHWAY

Apoptosis can be triggered by extracellular signals that activate cell surface death receptors of the tumor necrosis factor (TNF) receptor superfamily.^{6, 12} Members of this superfamily have cysteine-rich extracellular domains and exist as pre-assembled trimers. The best-characterized death receptors are the prototypical death receptor Fas (CD95, or Apo1) and TNFR1. Others include DR3 (Apo3), DR4, and DR5 (TRAIL-R2, or Apo2). Death receptors have cytoplasmic death domains (DD) that bind to DD-containing adaptor molecules through homotypic interactions (Fig. 14.2). The adaptor molecule FADD is crucial for signal transduction because it also possesses a death effector domain (DED). This domain enables FADD to bind homotypically to the initiator caspases-8/10, which also contain DED. Upon receptor-ligand binding, recruitment of caspases-8/10 into the large death-inducing signaling complex (DISC) causes their oligomerization and enzymatic activation. Clusters of DISC form higher-order signaling protein oligomerization transduction structures (SPOTS), which promote further caspase activation. This leads to downstream caspase cascade for cell death.

The extrinsic pathway can feed into the intrinsic pathway to amplify signals for death.¹³ Activated caspase-8 can cleave BID, a pro-apoptotic BH3-only BCL-2 family member analogous to the *C. elegans* *egl-1* gene. Truncated BID improves the binding of the pro-apoptotic multidomain BAX and BAK proteins to mitochondrial membranes, increasing mitochondrial permeability. Cells that depend upon this mitochondrial amplification for death receptor-mediated death include peripheral blood lymphocytes. By contrast, other cell types that exhibit more efficient DISC formation for caspase-8 and downstream caspase-3 activation die independently of mitochondrial involvement.

Engagement of death receptors can trigger cellular responses other than death. For example, Fas stimulation also activates the transcription factor NF- κ B and mitogen-activated protein kinases (MAPK) p38 and ERK1/2. Activation of these signaling pathways can counterbalance

Fig. 14.2 Extrinsic and intrinsic signaling pathways for apoptosis. Two pathways exist for activating the effector caspases for lymphocyte apoptosis induction and propioidal regulation. The extrinsic pathway activates initiator caspases-8 and -10 in death-inducing signaling complexes (DISC) anchored by death receptors. The intrinsic pathway activates initiator caspase-9 within the apoptosome. This structure is assembled when mitochondria are permeabilized. BCL-2 family members either facilitate or antagonize mitochondrial permeability and can link the intrinsic to the extrinsic pathway. See text for more details.

signals for death. However, Fas mutations generally impair death signals more readily than growth-promoting signals.

LYMPHOCYTE DEATH DURING AN IMMUNE RESPONSE

Mature peripheral lymphocytes vary in their susceptibility to apoptosis. Resting cells and cells undergoing initial activation are typically refractory to death. This property allows an effective immune response to develop against pathogens. Once cells proliferate and enter the late G1/S phase of the cell cycle, their sensitivity to death increases. The acquisition of death sensitivity occurs at the height of an ongoing immune response and at its conclusion. Thus, lymphocytes possess a built-in rheostat that can regulate cell death as a function of the rapidity by which the cells are progressing through the cell cycle.⁵

The sensitivity of lymphocytes to antigen-driven cell death during an immune response, termed propioidal regulation, is a major negative-feedback mechanism that can be used to control the intensity of immune responses. Two events contribute to antigen receptor restimulation-induced propioidal death (Fig. 14.3).⁵ First, high levels of antigen stimulate the production of high levels of interleukin (IL)-2, which drives lymphocytes into cell cycle. Cells respond by undergoing molecular changes that render them susceptible to the extrinsic pathway or “active” apoptosis. This process is independent of new protein or mRNA synthesis, but may involve increased Fas expression and downregulation of anti-apoptotic molecules such as c-FLIP. As a consequence, T and B lymphocytes are triggered to die when their Fas receptors interact with soluble or membrane-bound FasL. CD8 cells also die when triggered through their TNF receptors. In addition, the antigen receptor

appears to connect directly to the pro-apoptotic molecule BIM. This mechanism helps limit the magnitude of the immune response, and thereby protects the host in the presence of continuous or repeated antigenic stimulation.

The second mechanism contributing to death of lymphocytes occurs when an immune response wanes (Fig. 14.3).⁵ A falling level of antigen markedly decreases the amount of IL-2 produced. This in turn decreases CD25 – a component of the high-affinity IL-2 receptor complex whose expression is IL-2-dependent – and renders the cells increasingly nonresponsive to IL-2. Cytokine withdrawal drives the intrinsic pathway of apoptosis in a process that requires new protein and mRNA synthesis. Death can be blocked by the addition of common γ -chain receptor cytokines other than IL-2, such as IL-4, IL-7, and IL-15, or by overexpressing anti-apoptotic BCL-2/BCL-X_L proteins, which restrain apoptosis at the mitochondria. This mechanism facilitates contraction of the immune response following pathogen elimination.

In summary, actively cycling lymphocytes die by means of mechanisms that involve antigen receptor-induced death. These mechanisms are mediated partly by death receptors Fas and TNF, and partly by cytokine withdrawal. These complementary mechanisms limit the magnitude and duration of an immune response by eliminating activated cells.

IN VIVO IMPORTANCE OF APOPTOSIS

Studies in experimental animals and in humans have established that apoptosis is a normal physiological process that maintains immunologic tolerance and prevents development of autoimmunity.^{6,14} *Lpr* (lymphoproliferation) is a naturally arising mouse strain with a mutation in *Fas*

Fig. 14.3 Propriocidal regulation of actively cycling lymphocytes involves apoptosis induced (1) through death receptors at the height of the immune response, and (2) upon cytokine withdrawal at the end of the response.

resulting in its deficiency. Homozygous mutant mice develop splenomegaly and lymphadenopathy. Depending upon the genetic background, they also develop hypergammaglobulinemia, autoantibodies, glomerulonephritis, polyarteritis, sialoadenitis, arthritis, or primary biliary cirrhosis. Similar disease features are seen in another naturally arising mouse strain called *gld* (generalized lymphoproliferative disease), which has a homozygous Fas ligand (*FasL*) mutation. Recently, mice were generated in which the Fas death receptor pathway was selectively blocked in different immune cells.¹⁵ Surprisingly, disease was more severe in the mice with Fas-blocked dendritic cells as compared to lymphocytes. Dendritic cell numbers and APC function were enhanced. The death of dendritic cells, acting in concert with propriocidal death of lymphocytes, may enforce tolerance and prevent autoimmunity *in vivo*.

THE AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

CLINICAL FEATURES

In 1992, Sneller and colleagues²⁸ described a childhood syndrome of immune cell dysregulation including autoimmunity, hypergammaglobulinemia, lymphadenopathy, and lymphocytosis. The lymphocytosis reflected expansion of an unusual T-cell population bearing rearranged T-cell receptor (TCR)- α/β but lacking CD4 or CD8 co-receptor expression (double-negative T cells; DNT). This constellation of findings resembled key phenotypic features of *lpr* and *gld* mouse strains, natural models of autoimmune disease later found to harbor *Fas* and *FasL* mutations, respectively. Like *lpr* mice, these patients had *FAS* mutations leading to the defective lymphocyte apoptosis that was critical for disease pathogenesis. The human disease was

CLINICAL RELEVANCE

- >> Autoimmune lymphoproliferative syndrome (ALPS) is a genetic disorder that impairs lymphocyte apoptosis
- >> Mutations in *TNFRSF6* (*FAS*) underlie most cases of ALPS:
 - A minority of ALPS is caused by mutations in *TNFRSF6* (Fas ligand), *CASP10* (caspase 10), or somatic *FAS* mutations affecting DNT cells
 - These mutations all impair the Fas-mediated extrinsic pathway of apoptosis
 - Most are dominant interfering because they prevent formation of an effective death-inducing signaling complex (DISC)
- >> ALPS can also result from a defect in the cytokine withdrawal-induced intrinsic pathway of apoptosis:
 - A dominant *NRAS* gain-of-function mutation that prevents BIM induction can be responsible
- >> ALPS predisposes to autoimmunity and lymphomas:
 - The most typical autoimmune findings are autoantibodies, Coombs-positive hemolytic anemia, or chronic idiopathic thrombocytopenic purpura
 - Hodgkin and non-Hodgkin lymphomas both occur
- >> Caspase-8 deficiency state (CEDS) is characterized by combined lymphocyte immunodeficiency with susceptibility to infection, superimposed upon ALPS-like features of lymphoproliferation and apoptotic defects:
 - These findings stem from the participation of caspase-8 in two different signaling complexes – one for death induction, and another for NF- κ B activation

KEY CONCEPTS

DIAGNOSTIC CRITERIA FOR AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME (ALPS)

Required criteria

- >> Chronic nonmalignant lymphadenopathy and/or splenomegaly
- >> Increased peripheral CD4⁺CD8⁺TCR α/β (DNT) cells
- >> Lymphocyte apoptosis defect

Supporting criteria

- >> Family history of ALPS
- >> Characteristic histopathology
- >> Autoimmune manifestations
- >> Mutations in *FAS*, *FASLG*, *CASP10*, *NRAS*

therefore termed autoimmune lymphoproliferative syndrome (ALPS), and is likely the same clinical entity characterized in descriptive accounts by Canale and Smith²⁹ and others in the earlier literature.

ALPS is a rare condition with variable disease penetrance, affecting a reported 300 persons worldwide. Diagnostic criteria, discussed below, reflect deranged lymphocyte homeostasis.^{6, 8, 16, 17} Patients must present with chronic nonmalignant lymphocyte accumulation, including lymphadenopathy and/or splenomegaly, elevated DNT numbers in peripheral blood, and defective *in vitro* lymphocyte apoptosis. Autoimmunity is often seen, or more rarely lymphoma, but these are not required for diagnosis.

Signs and symptoms of ALPS usually emerge in infancy or early childhood (median age of 24 months), when patients undergo medical investigation for unexplained splenomegaly, lymphadenopathy, or autoimmune destruction of blood cells. Typically there is painless enlargement of peripheral lymphoid organs, and no fever or weight loss unless complicated by lymphoma. The thymus or liver can also be enlarged. Although lymphoid hyperplasia can fluctuate, even without treatment it tends to improve gradually with age. Up to 80% of ALPS patients have circulating autoantibodies, although only half have actual autoimmune disease. Coombs-positive hemolytic anemia and chronic immune thrombocytopenic purpura are the most common autoimmune diseases. These manifestations tend to be severe, but often follow a variable course. When seen at initial presentation, ALPS can be mistaken for Evans syndrome. Neutropenia due to hypersplenism or autoimmunity can occur, but is usually mild. The high incidence of anti-cardiolipin or anti-neutrophil antibodies has no correlation with clinical manifestations of thrombosis or neutropenia. Rare autoimmune manifestations include antinuclear antibodies, rheumatoid factor, glomerulonephritis, optic neuritis or uveitis, Guillain-Barré syndrome, primary biliary cirrhosis, anti-factor VIII antibodies with coagulopathy, autoimmune hepatitis, vasculitis, and linear immunoglobulin A (IgA) dermatopathy.

DNT expansion is peculiar to and required for diagnosis of ALPS. Normally, DNT comprise less than 1% of lymphocytes in the peripheral blood or in lymphoid tissues. However, they can reach up to 40% in ALPS patients. These cells are distinct from the immature DNT cells developing in the thymus that have not yet rearranged their TCR genes or expressed TCR on their cell surface. They are thought to represent aging mature

CLINICAL PEARLS

- >> Classification is based upon findings that may be present or have resolved
- >> Despite its moniker, at least one-fifth of patients with autoimmune lymphoproliferative syndrome (ALPS) lack evidence of autoimmunity
- >> Variable penetrance means that not all individuals with mutations manifest disease
- >> TCR γ/δ cells lacking CD4 and CD8 co-receptors may falsely elevate the double-negative T-cell (DNT) count
- >> Expression of B220 on DNT cells is a finding specific to ALPS
- >> Elevated B₁₂ levels can be used as a simple screen
- >> Other helpful laboratory findings are hypergammaglobulinemia, direct Coombs test, or anti-cardiolipin antibodies
- >> Patients without known mutations should be directly analyzed for somatic mutations in sorted DNT cells:
- >> Apoptosis cannot be readily assessed by the usual methods, because DNT cells cannot be maintained in culture

T cells that have lost CD4 or CD8 co-receptor expression, but the details of their origin are obscure. DNT express the CD45R isoform B220, a marker normally found on B cells, as well as CD27, CD57, and HLA-DR. In ALPS patients the expanded DNT produce high levels of IL-10. As elevations in IL-4 and IL-5 are also seen, the resulting T helper type 2 (Th2) cytokine profile probably contributes to the observed polyclonal hyperglobulinemia and autoantibodies. The demonstration that some ALPS patients are mosaics – with *Fas* mutations in DNT but not all T cells – implicates DNT in disease pathogenesis. However, understanding their exact function has been hampered by an inability to keep them alive in culture, as they do not respond well to most activating and proliferative stimuli.

Lymphoproliferation in ALPS is not limited to DNT. Patients have increased numbers of total T cells, with contributions from CD8 cells expressing CD57 as well as TCR γ/δ ⁺ cells that lack CD4 and CD8 expression. Both total B cells and CD5⁺ B cells are increased. By contrast, CD4⁺CD25⁺ T cells are low, resulting in no overall change in CD4 cell numbers. Natural killer (NK) cell numbers are also unchanged. Lymph node biopsy reveals a characteristic histopathology showing follicular hyperplasia with polyclonal plasmacytosis, and paracortical expansion with infiltrating DNT.¹⁸ Besides lymphocyte immunophenotyping, high levels of circulating cobalamin (vitamin B₁₂) can be used as a simple initial screening test for ALPS. However, by itself it cannot differentiate from certain other hematologic disorders, including lymphoproliferative and myeloproliferative disorders (VK Rao, JK Dale, and SE Straus, personal communication).

A definitive diagnosis of ALPS requires the evaluation of lymphocyte apoptosis *in vitro*, a test that is typically performed only in specialized research laboratories. A key point for the appropriate interpretation of this test is that cells must be proliferating well in order to become susceptible to death-inducing stimuli. Thus, poor proliferation can be falsely interpreted as an apparent apoptosis resistance. Peripheral T cells can be activated with phytohemagglutinin and then driven into

cell cycle by culturing with IL-2. Fas agonistic antibodies or TCR restimulation can then be used to induce apoptosis. A flow cytometer is subsequently used to count propidium iodide-excluding cells ('live' cells) over constant time. This number is compared to that for untreated cells, enabling calculation of the percent cell loss at any given dose of stimulus. A decrease in percent cell loss at half of normal controls is usually considered evidence of an apoptosis defect.

Although initially nonmalignant, the lymphoproliferation in ALPS predisposes to lymphoid malignancy, which develops in 10% of ALPS patients. In rare instances, ALPS patients are diagnosed when they initially present with lymphoma. Compared to the general population, ALPS patients with *FAS* mutations (type 1A) have a 51-fold and 14-fold elevated incidence of Hodgkin and non-Hodgkin lymphoma, respectively. Median age of diagnosis was 11 years for Hodgkin lymphoma and 21 for non-Hodgkin lymphoma; however, lymphomas were identified anywhere between 2 and 50 years of age. Lymphomas are of either B- or T-cell origin and of diverse histological type, thus betraying a general anti-neoplastic role for propioidic death of lymphocytes. The lymphomas display neither loss of heterozygosity for the Fas mutation nor increased resistance to apoptosis. Most patients who develop malignancy have mutations in the DD region, with severe impairment in Fas-mediated lymphocyte apoptosis but continued Fas-mediated activation of NF- κ B and MAPK for growth promotion. MAPK hyperactivation, coupled with impaired cytokine withdrawal-mediated apoptosis, was also associated with lymphoma in an individual with ALPS type IV due to *NRAS* mutation.²⁵

MOLECULAR ETIOLOGY AND CLASSIFICATION

A proposed ALPS classification based on underlying genetic defects is presented in Table 14.1 and the corresponding molecular mechanisms are discussed below.^{6, 8, 16}

Most ALPS patients bear heterozygous mutations in the *FAS* (*TNFRSF6*) gene located on chromosome 10q24.1. Mutations can be found throughout the gene, either in coding regions or in splice sites, with the majority (~2/3) affecting the intracellular DD encoded by exon 9. (A description of all mutations can be found in the ALPS database: ALPSbase: <http://research.nhgri.nih.gov/ALPS/>.) Autosomal dominant disease transmission occurs because most mutations exert a dominant interfering effect. This effect is explained by understanding that pre-association of three normal Fas molecules in a trimer is required for receptor death signaling function (Fig. 14.2). If 50% of Fas proteins are abnormal, as is the case for heterozygous mutations, seven out of eight Fas trimers would contain at least one mutant protein, rendering that trimer ineffective. Severity is greatest for DD mutations, which disrupt the homotypic interactions required for FADD and initiator caspase recruitment into the death-inducing signaling complex (DISC). Those that do not affect DISC formation can impair downstream higher order signaling protein oligomerization transduction structures (SPOTS) formation, which is necessary for efficient caspase activation. A few ALPS patients have compound heterozygous loss-of-function mutations that cause haploinsufficiency. Individuals with complete loss of function due to homozygous mutations have generally more severe symptoms. ALPS patients with *FAS* mutations are classified as type Ia. In some ALPS patients, *FAS* somatic mutations have been found in purified DNT cells and a fraction of peripheral lymphocytes, monocytes and hematopoietic precursors. Notably, their (non-DNT) T cells lacked

FAS mutations and apoptosis defects when expanded *in vitro*. These patients are provisionally classified as type I_m (for 'mosaic').

A minority of ALPS patients harbor mutations in other components of the Fas pathway. A heterozygous mutation in Fas ligand (*FASLG*, *TNFSF6*) was originally reported for a patient with systemic lupus erythematosus who had lymphadenopathy, splenomegaly, and defective lymphocyte apoptosis after TCR restimulation, but no apparent DNT expansion. However, ALPS patients were also discovered who possessed either heterozygous²⁶ or homozygous *FASLG* mutations,¹⁹ and these are classified as type 1b. Although caspase-10 functional polymorphisms may influence disease, at least two heterozygous caspase-10 mutations in 3 ALPS patients have been identified that cause defective apoptosis in lymphocytes and dendritic cells.²⁰ These patients have been classified as type II.

A subgroup of ALPS patients fulfills diagnostic criteria including increased DNT, but lacks detectable Fas-mediated apoptosis defect or known mutations in the Fas pathway. These have been termed type III. We have recently identified one such patient who demonstrated defective lymphocyte apoptosis upon cytokine withdrawal, a stimulus that triggers the intrinsic pathway. A gain-of-function mutation in the gene *NRAS* resulted in diminished downstream expression of BIM, which accounted for failure to induce apoptosis. This is the first reported defect in the intrinsic pathway of apoptosis causing ALPS.²⁵

The relationship between genotype and phenotype is complex. Gene mutations are required, but are not sufficient for disease. In large kindreds, family members with the same mutation and degree of defective *in vitro* Fas-mediated apoptosis had very different clinical manifestations. In-depth analysis revealed that penetrance was greatest with intracellular DD mutations and least with extracellular mutations. This indicates that other factors, genetic and/or environmental, influence the clinical phenotype.

ALPS-LIKE DISEASE

Some patients have features overlapping with but not fulfilling diagnostic criteria for ALPS.⁶ For instance, the ALPS-variant autoimmune lymphoproliferative disease (ALD) has lymphoproliferation, autoimmune disease, susceptibility to cancer, and defective lymphocyte apoptosis, but lacks DNT expansion. The responsible molecular defects are unknown. In another cohort patients display clinical features of ALPS but lack apparent apoptosis defects. Apoptotic defects are usually assessed through the Fas death receptor, which may not reveal defects that would be seen if induced by other stimuli. Apoptotic defects may also not be readily apparent due to the cells used for analyses, for example, in somatic mosaicism. Given recent evidence that dendritic cell apoptosis defects can contribute to disease pathogenesis,¹⁵ we speculate that other diseases resembling ALPS, such as Rosai-Dorfman disease, may involve mutations within APC.²¹ In sum, a proportion of ALPS-like disease likely represents variants of ALPS. However, other forms of ALPS-like disease probably reflect abnormalities in nonapoptotic pathways that also regulate lymphocyte growth and activation.

There is a growing realization that certain molecules involved in apoptosis also function integrally for lymphocyte growth and activation. One such molecule is caspase-8. Its deficiency, found in two siblings with homozygous mutations, leads to an immune regulation syndrome we term caspase-8 deficiency state (CEDS).²² Consistent with the known role of caspase-8 as an initiator caspase in the DISC, these patients had mild lymphadenopathy and splenomegaly, as well as lymphocyte apoptotic defects. However, they had inconsistent marginally elevated

Table 14.1 Autoimmune lymphoproliferative syndrome (ALPS) classification by molecular defect

Classification	Genetic defect
Type Ia	<i>FAS</i> (<i>TNFRSF6</i>)
Type Ib	<i>FASLG</i> (<i>TNFSF6</i>)
Type Im	Somatic <i>FAS</i> mutations
Type II	<i>CASP10</i>
Type III	Unknown mutation
Type IV (provisional)	<i>NRAS</i> (defective intrinsic apoptosis)

THERAPEUTIC PRINCIPLES

AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME (ALPS)

- >> Disease can improve with age
- >> Corticosteroids are useful for rapidly bringing autoimmune disease under control
- >> If unable to discontinue medications, low-dose corticosteroids given every other day, or mycophenolate mofetil, may be useful in preventing recurrence of autoimmune disease
- >> Splenectomy should only be considered when hypersplenism contributes to severe refractory cytopenias
- >> The risk of post-splenectomy sepsis necessitates lifelong antibiotic prophylaxis
- >> Cytotoxic agents or matched unrelated donor allogeneic bone marrow transplantation can be considered for worst-case scenarios
- >> Patients should undergo periodic monitoring for development of lymphoma
- >> When they develop, ALPS lymphomas tend to respond to conventional therapies

DNT, raising doubt as to whether they fulfilled ALPS criteria. More importantly, unlike classical ALPS patients, the CEDS patients had a prominent combined immunodeficiency with recurrent sinopulmonary infections and mucocutaneous herpes virus infections. They had low serum immunoglobulin levels and poor humoral responses to polysaccharide antigens, as well as impaired activation of T cells, B cells, and NK cells. Thus, they resembled patients with common variable immunodeficiency (CVID). We recently found that the impaired lymphocyte activation resulted from a defect in the kinetics of activation of the critical transcription factor NF- κ B in response to stimulation through antigen receptors, TLR-4, and Fc γ RIII.²² This is because caspase-8 participates in a signaling complex that includes other proteins such as BCL-10, MALT-1, and IKK in an NF- κ B-activating signalosome. This complex differs from the DISC and is not affected in classical ALPS patients. It will be important to identify other patients with caspase-8 deficiency to allow further definition of the clinical spectrum of this disease.

APOPTOSIS IN OTHER IMMUNODEFICIENCIES

Although resting lymphocytes are relatively resistant to death, they appear to require antigen receptor expression with continuous low or intermittent stimulation, in addition to homeostatic cytokines such as IL-7 and IL-15 for survival.^{5,13} Mice rendered genetically deficient in anti-apoptotic BCL-2 family members (such as BCL-2, BCL-X, and MCL-1), show loss of mature or developing lymphocytes. These results suggest that inappropriately activated intrinsic pathways of apoptosis may contribute to immunodeficiency. Several studies demonstrated increased spontaneous apoptosis of lymphocytes from patients with CVID, ataxia-telangiectasia, adenosine deaminase-severe combined immunodeficiency (ADA-SCID), Omenn's syndrome, cartilage-hair hypoplasia, and DiGeorge syndrome. However, without defining biochemically how specific gene mutations affect apoptosis, it is difficult to know whether these associations are simply correlative or indeed causative.

THERAPIES FOR ALPS

Although symptoms can remit with age, some ALPS patients require continued treatment to control autoimmune disease.^{17,23} Treatment for autoimmune cytopenias is similar to that used in patients without ALPS. A high-dose pulse of corticosteroid (5–30 mg/kg methylprednisolone i.v.) is useful in bringing autoimmune cytopenias rapidly under control. This is followed by a low-dose course (1–2 mg/kg prednisone orally) that can be tapered and eventually discontinued after several weeks to months. Adjuncts to corticosteroids include intravenous immunoglobulin for autoimmune thrombocytopenia or hemolytic anemia, and granulocyte colony-stimulating factor (G-CSF, 1–2 μ g/kg from three times a week to once daily) for autoimmune neutropenia. In some patients, autoimmune disease promptly recurs after discontinuing corticosteroids. These patients may need to be maintained on a minimal dose every other day. Alternatively, such patients may benefit by switching to the immunosuppressant mycophenolate mofetil (~600 mg/m² per dose orally, twice daily) for long-term maintenance therapy. The long-term corticosteroid- and splenectomy-sparing effects of this agent are particularly advantageous in children. For patients who fail these approaches, cytotoxic agents can be tried. Success has been reported using azathioprine, vincristine, or rituxan (anti-CD20 monoclonal antibody, 375 mg/m² per week i.v. \times 4), although no controlled prospective trials exist to support the widespread use of these drugs in ALPS patients. Allogeneic bone marrow transplantation has been curative when undertaken in the rare instances of severely and intractably affected patients with homozygous *FAS* mutations and complete absence of Fas. However, given the associated high risks of complications and death, use of matched unrelated donor allogeneic bone marrow – which is likely to be required to avoid repopulating with lymphocytes from family members having the same mutation – should be considered a therapy of last resort.

Although lymphadenopathy and splenomegaly may be unsightly, these disease manifestations are usually not treated unless medically indicated. Hypersplenism can contribute to low blood cell counts when splenic pooling exacerbates autoimmune-mediated destruction. Notably, none of the current agents used to treat ALPS improves lymph node or spleen size. Splenectomy may be required if immunosuppressant

agents fail to improve cytopenias. A disproportionately increased risk for post-splenectomy pneumococcal sepsis and death in ALPS patients means that splenectomy should be undertaken only after extensive discussions with the patient and family. Patients should be immunized with vaccines against *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis* before splenectomy. Following splenectomy, patients should be re-immunized with conjugate plus polysaccharide pneumococcal vaccines when titers wane. Lifelong antibiotic prophylaxis with penicillin or fluoroquinolones is essential. Moreover, splenectomized patients should be instructed to seek immediate medical attention to rule out bacteremia during febrile illnesses.

Given that treatment of ALPS patients aims primarily at controlling autoimmune manifestations, drugs that control lymphoproliferation or prevent lymphomagenesis are needed. Several case reports suggested that sulphadoxine-pyrimethamine (Fansidar) treatment might have utility in patients with ALPS or ALPS-like disease. Regression of lymphadenopathy and/or splenomegaly, as well as improvement in blood cell counts, were observed in 6 of 7 treated patients. Two of the treated patients sustained remission after discontinuing the drug. However, more recent studies in ALPS patients and the *lpr* mouse model failed to demonstrate any significant benefit of this agent or pyrimethamine alone on lymph node or spleen size.²⁷ Therefore, at present this regimen cannot be considered recommended therapy.

Finally, the predisposition to lymphoma presents a unique clinical challenge: how to distinguish a newly developing or relapsed lymphoma from benign lymphadenopathy. ALPS patients require careful periodic examinations and surveillance by serial computed tomography scans. Suspiciously enlarging lymph nodes may necessitate biopsy to assess for clonality and chromosomal abnormalities. Positron emission tomography scans, which detect areas of high cellular glucose uptake, are useful for identifying and following suspicious lesions.²⁴ Fortunately, lymphomas in ALPS patients tend to respond to conventional therapies.

CONCLUSION

Programmed cell death is an essential regulatory mechanism to establish equipoise with growth, differentiation, and proliferation of lymphocytes. Studies in humans with the rare genetic disorder ALPS have demonstrated that apoptosis is physiologically important for maintaining lymphocyte homeostasis, preventing autoimmunity, and suppressing lymphomagenesis. Studies in ALPS-like disorders such as CEDS have revealed that molecules responsible for death can also participate in other intracellular signaling pathways for normal lymphocyte function. Defining the genetic abnormalities responsible for ALPS and related disorders should continue to provide insights into the mechanisms that regulate immune cell homeostasis *in vivo*.

Immunoglobulin function

Neil S. Greenspan

15

Antibody-mediated immunity generally requires noncovalent contact between antibody and antigen. The ability of an antigen to bind noncovalently to an antibody, referred to as *antigenicity*, is a physicochemical property evaluated with respect to a given antibody population. In contrast, *immunogenicity*, the ability to induce the biosynthesis and secretion of soluble antibody molecules, is a biological property, typically evaluated *in vivo* with respect to a particular immune system. Although antigenicity is necessary for immunogenicity, it is not sufficient. Moreover, the immunogenicity of a given molecule or molecular complex is influenced by host genetic variation. For example, a vaccine may be highly immunogenic in one person but be weakly immunogenic or nonimmunogenic in another.

When an antibody binds to a macromolecular antigen it directly contacts only a portion of the molecular surface of that antigen, not the entire molecule or molecular complex. Similarly, only a portion of the antibody molecule makes direct contact with the antigen. By convention, the portion of an antibody or T-cell receptor that makes physical contact with an antigen is referred to as the *paratope* or combining site. Most of the amino acids in an antibody variable domain that contact a given antigen are located in the hypervariable regions (also referred to as complementarity-determining regions or CDRs). However, X-ray crystallographic analyses of antibody–protein antigen complexes have shown that some contact residues reside in the framework regions.¹ The region of the antigen that is in physical contact with the paratope is conventionally called the *epitope* or antigenic determinant.

Although an epitope (paratope, etc.) is usually defined in terms of intermolecular contact, the region of a molecule involved in physical contact with another molecule may not correspond exactly to the structural correlates for energetics and specificity.²

■ ANTIGEN BINDING AND MOLECULAR IDENTITY ■

PHYSICAL ASPECTS OF BINDING

Antibody–antigen interactions are, with rare exceptions, *noncovalent*. The significance of this point is that these interactions are, in principle, spontaneously reversible under the conditions of temperature, pressure, pH, and ionic strength that generally prevail in living organisms.

Several types of noncovalent bond have been shown to contribute to antibody–antigen binding. These include van der Waals forces, hydrogen bonds, ionic bonds, and hydrophobic interactions. All of these bonds individually provide forces in the range of one to a few kcal/mol, versus 50–100 kcal/mol for covalent bonds. Because the potential to engage in these types of bond is shared by many of the components of biological macromolecules (e.g., amino acids, monosaccharides, and fatty acids), individual weak bonds do not usually confer a high degree of specificity. For example, any two atoms can interact through van der Waals forces. It is only through the simultaneous action of many such bonds that molecular specificity arises. Hence the importance of a close fit, often referred to as *complementarity* (or complementariness), between the antigen epitope and the antibody paratope.

Complementarity will be maximized when one molecule is concave and the other is convex; when one molecule is positively charged and the other is negatively charged; and where one has a hydrogen bond donor whereas the other offers a hydrogen bond acceptor, etc. It is expected that greater complementarity between receptor and ligand will in general be associated with a stronger interaction (greater affinity) between the two molecules. Specificity (see below) is also expected to be related to complementarity.³

In rationalizing the strength of interactions between antibodies and antigens, or other receptors and ligands, it is important to remember that the receptor competes with solvent for binding to ligand. Therefore, the thermodynamics of the interaction between two structures reflects the influence of the interaction on the solvent and other solutes, and not just the complementarity between the two molecules of special interest. Furthermore, bound water molecules may make important – even crucial – contributions to an interaction between two macromolecules or an interaction between a macromolecule and a small molecule. Apparently subtle modifications of structure can alter the thermodynamic balance (extent of binding) or the qualitative features of contact between receptor and ligand such that the agonist (e.g., a potent immunogen) becomes an antagonist or an inactive analogue (a poor immunogen).

The types of weak bond described above, and the concept of complementarity between interacting molecules, are relevant to our understanding of noncovalent interactions that can involve any biological molecules, including (but not limited to) the interactions between a T-cell receptor,

Table 15.1 Antigens and valence (Adapted from Benjamini E, Leskowitz S. Immunology: a short course, 2nd edn. New York : Wiley-Liss, 1991, with permission from Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

Number of types of epitope	Epitope copy number	Examples
Monodeterminant	Monovalent	Hapten: DNP, digoxin
Monodeterminant	Multivalent	Polysaccharide: dextran*
Multideterminant [#]	Monovalent	Monomeric protein: myoglobin
Multideterminant	Multivalent	Virion: influenza virus

*Even a polysaccharide composed of one type of hexasaccharide can have two or more different kinds of epitope: terminal versus internal residues, for instance. However, a given antiserum may preferentially contain antibodies specific for only one such epitope.

[#]Typically, multideterminance can only occur with respect to a polyclonal antibody.

its nominal antigen peptide, and an MHC class I or class II molecule; CD8 and MHC class I; CD4 and MHC class II; HIV gp120 and CD4; and LFA-1 and ICAM-1. Therefore, antibody recognition of antigen serves as a paradigm for understanding molecular recognition in the immune system in general. As will be discussed below, this fact, coupled with the inducibility of antibodies, permits antibodies to be used as surrogate ligands for almost any receptor (or vice-versa).

Affinity is the concept we use to convey how strongly two molecules bind to each other. In Table 15.1, antibody–antigen interactions are categorized with respect to the numbers of different kinds of paratope–epitope bonds and the absolute number of such bonds of each kind. Reflecting the different types of antibody–antigen interaction so identified, two categories of affinity merit consideration: *intrinsic affinity* and *functional affinity*. It should be noted that some immunologists prefer to use the term ‘avidity’ in place of ‘functional affinity.’

Intrinsic affinity is a measure of the strength of the *monovalent* interaction between a particular paratope or antibody–combining site and a particular epitope or antigenic determinant, under defined conditions of temperature, pressure, ionic strength, and pH. By convention, the intrinsic affinity is taken to be the equilibrium association constant characterizing the paratope–epitope pair. If paratopes are represented by P, monovalent epitopes by E, paratope–epitope complexes by PE, and the equilibrium association constant by K_A , then, by the Law of Mass Action:

$$K_A = \frac{[PE]}{[P][E]}$$

The above equation says that the intrinsic affinity is the reciprocal of the concentration of monovalent antigen at which half of the paratopes will be occupied. Thus, this approach to measuring the strength of the interaction between paratope and epitope does so by determining how likely it is that epitope and paratope will be found in a complex.

Note that the intrinsic affinity, defined as above, is not an intrinsic property of either the paratope or the epitope. Instead, an intrinsic affinity characterizes the relationship between two molecules under defined conditions.

The intrinsic affinity of an antibody for a small antigenic molecule (hapten) can be determined by the technique of equilibrium dialysis (Fig. 15.1). This technique uses a semipermeable membrane to separate

two compartments, one containing hapten and the other containing hapten and antibody. This membrane is referred to as semipermeable because the hapten can diffuse across it, but the antibody cannot. Free hapten will diffuse between the two compartments, and eventually the rate of diffusion between the compartments will be the same in both directions (dynamic equilibrium). At this point, the concentration of free hapten will be identical in the two compartments, but the compartment containing antibody will have more total hapten (free plus bound). By using haptens in chemical forms (e.g., radioactive) that permit quantification, one can determine the fraction of paratopes bound at known concentrations of hapten and antibody at specified temperature, pressure, ionic strength, and pH. This information permits the calculation of the intrinsic affinity.

The intrinsic affinity of an antibody for a small molecule, such as a drug (e.g., digoxin) or a hormone (e.g., insulin), can be clinically important both *in vivo* and *in vitro*.⁴ For example, the *in vivo* effectiveness of antibody Fab fragments in removing toxic levels of the drug digoxin from the bodies of patients being treated for congestive heart failure is likely to be partially dependent on the intrinsic affinity of the Fab fragments for the drug. Alternatively, antibody intrinsic affinity can limit the analytical sensitivity of an *in vitro* immunoassay designed to determine the concentration of an analyte, such as a hormone (e.g., insulin, parathyroid hormone), or a drug (e.g., digoxin).

Functional affinity is defined as the equilibrium association constant characterizing the interaction between an intact antibody and an intact antigen. For a monovalent IgG antibody–antigen interaction, the intrinsic affinity and the functional affinity will be the same. However, if two paratopes interact simultaneously with two epitopes on the same antigen, which is referred to as *monogamous bivalency* (Fig. 15.2), the functional affinity of the antibody for the *multivalent* antigen may be substantially greater (as much as 10,000-fold for IgG) than the intrinsic affinity of that antibody for the relevant epitope on that same antigen.⁵ Functional affinity is also influenced by the degree to which the geometric relationships among the epitopes are optimal for the paratopes, which will depend on the quaternary structure and segmental flexibility of the antibody molecule. In the presence of nonoptimal geometry, the average number of engaged sites may be less than maximal, and energy may be expended in achieving some epitope–paratope contacts. Therefore, the functional affinity for a multivalent interaction cannot necessarily be predicted precisely from the intrinsic affinity and the

Fig. 15.1 Measurement of the intrinsic affinity characterizing an interaction between antibody and antigen (hapten) by equilibrium dialysis. At equilibrium, the amount of diffusible free hapten inside the dialysis bag will be equal to the amount of free hapten outside the bag. In the presence of antibody (B), therefore, the total hapten concentration will be greater inside of the dialysis bag (free + antibody-bound) than outside of the bag (free). The extent of this difference can be used to determine the intrinsic affinity of the antibody for the hapten. (From Abbas AK, Lichtman AH, Pober JS. Cellular and molecular immunology. WB Saunders Company, 1991 with permission from Elsevier.)

maximal number of binding sites that can be engaged simultaneously by an antibody molecule.

Intrinsic affinity provides information, with the qualifications noted above, on the degree of complementarity between epitope and paratope. Functional affinity takes account of properties influenced by structural features outside of the epitope and paratope, as normally conceived. Both concepts of affinity are valuable. Maximization of intrinsic affinity may be of prime importance for antibody-mediated inactivation of toxins or enzymes, which frequently involve monovalent interactions. In cases where antibodies bind to repetitive antigens or epitopes on the surfaces of bacteria, viruses, fungi, parasites, or mammalian cells, the functional affinity is likely to be a key factor influencing the biological consequences of the interaction.

In some instances, bivalent (IgG, IgE) or multivalent (IgA, IgM) antibodies may bind simultaneously to two or more epitopes on different antigenic particles, cross-linking them rather than engaging in monogamous bivalency or monogamous multivalency (Fig. 15.2). This phenomenon has played an important historical role in immunology. It is the basis for assays that make use of precipitation or agglutination of antigens by antibodies. Clinical methods for typing erythrocyte antigens (e.g., ABO and Rh antigens) still rely on agglutination of red cells by antibodies (or lectins).

IMMUNOLOGICAL SPECIFICITY

The concept of specificity is fundamental to an understanding of interactions between immunological receptors and antigens, but there are several senses of specificity in immunological contexts.⁶ These are delineated below.

One sense of specificity is focused on the goodness of fit between paratope and epitope. Intrinsic affinity is regarded as a reasonable measure of this goodness of fit. However, substantial conformational adjustments of either paratope or epitope may be necessary for formation of the complex.⁷ Such conformational changes will generally incur energetic costs. Consequently, intrinsic affinity and final complementarity may not be perfectly correlated.

A second sense of specificity corresponds to the ability of a paratope to distinguish between different epitopes. Such specificity is most readily studied when the epitope is in monovalent form. A quantitative measure of this kind of specificity is the ratio of intrinsic affinities characterizing, respectively, a paratope binding to the cognate ligand and the same paratope binding to a second ligand. This form of specificity can only be evaluated relative to a specified set of ligands. Thus, one should be cautious about extrapolating claims that one antibody is more or less specific than another with no reference to the relevant universe of ligands. However, there may be cases where it is justifiable to speak globally of more- or less-specific antibodies. Polyspecific antibodies have been described in the neonatal primary repertoire.⁸ These antibodies appear to be globally less discriminating than antibodies typical of the immune repertoire (secondary or later response) when tested on large panels of antigens.

Nevertheless, it is important to note that even antibodies derived from secondary (or later) responses are not,⁹ and cannot be, absolutely specific.^{10,11} The impossibility of perfect recognition or discrimination can be understood in both thermodynamic and structural terms. First, perfect fit and absolute discrimination would imply infinite intrinsic affinity (negative free energy change of complex formation), which is not physically plausible.¹⁰ Second, the convexity of atoms prevents perfect shape complementarity between antibody (receptor) and antigen (ligand).¹¹ Recent results also indicate that at least some antibodies can adopt two or more different unbound conformations, each of which exhibits a different ligand-binding profile. Such paratopes may undergo further structural adjustment in the process of binding to an epitope.¹²

In contrast to the epitope-centered forms of specificity just described, a third aspect relates to the ability of an antibody to discriminate among antigens that display many copies of one or more distinct epitopes. An antigen expressing many copies of one epitope is termed *multivalent*, and an antigen that expresses two or more structurally distinguishable epitopes is referred to as *multideterminant* (Table 15.1). Because two different cells, bacteria, viruses, etc., may both express multiple copies of the same or nearly the same epitope, an antibody that is highly specific (in the first sense above) for such a shared epitope may be a poor discriminator between such multivalent particles.⁶ Yet an

Fig. 15.2 Interaction of a bivalent antibody, such as IgG, with multivalent antigens can result in monovalent binding (A) monogamous bivalent binding (B) or cross-linking (C). The complexes in (B) are referred to as cyclic antibody–antigen complexes. (With permission from Eisen HN. General immunology. JB Lippincott, 1990.)

KEY CONCEPTS

BINDING OF ANTIBODY TO ANTIGEN

- >> Paratopes interact with epitopes through multiple noncovalent (weak) bonds, each of which is reversible at room temperature.
- >> Intrinsic affinity is taken to be the equilibrium association constant for a monovalent epitope-paratope interaction. It is a measure of the strength of that interaction and is influenced by the degree of complementarity between epitope and paratope and by ambient conditions: temperature, pressure, ionic strength, and pH.
- >> Functional affinity is a measure of the average strength of the interaction between an intact antibody and a multivalent antigen. It can be influenced by the spatial distribution of the epitopes that are being recognized.
- >> Intrinsic affinity and functional affinity can both be of biological importance, although both are not necessarily relevant in the same circumstances.
- >> For the clinician, immunological specificity may sometimes need to be evaluated primarily with respect to biological as opposed to physical endpoints.

antibody with a relatively poor degree of complementarity and intrinsic affinity for an epitope found on only one of two or more multivalent targets may be superior at discriminating among these antigens. Furthermore, antibodies (or other molecules) expressing two or more binding sites of identical structure may not discriminate identically among antigens displaying the same epitope in different two- or three-dimensional distributions.⁶

Some final points regarding specificity. First, in discussing interactions between molecules such as CD4 and MHC class II, which are not clonally distributed, it is common to describe such molecules as non-specific, meaning not specific for an antigen under consideration. The

contrast being drawn is with the antigen-specific receptors, Ig or TCR. However, from the point of view of the first or second category of specificity described above (goodness of fit, discrimination between ligands), the interaction between molecules such as CD4 and MHC class II may be as biochemically specific as that between an antibody and a class II molecule. Ideally, this sense of ‘nonspecific’ should be modified by the term ‘antigen.’ If not, the meaning must be inferred from the context. Second, for many purposes immunological specificity has an ultimately biological, not a physical, definition. If the endpoint of analysis is the triggering of a complex response, such as cell activation or initiation of the complement cascade, then the presence, absence, or extent of that response, and not the extent of receptor–antigen interaction, will be the ultimate criterion for evaluating specificity. Such biological specificity is not always directly correlated with specificity as determined by the analysis of binding.⁶ Third, the enormous utility of antibodies is crucially dependent on the discriminatory abilities of these molecules with respect to other molecules or molecular aggregates. However, given that the discrimination mediated by antibodies is not absolute, the usefulness of a particular antibody may depend on the context: which antigens or potential antigens in addition to the preferred target are available for binding to the antibody? Fourth, apparent antibody specificity may vary with the methods used for analysis, as these methods may differ in sensitivity and the conditions (pH, ionic strength, temperature) of application, such that the relevant intrinsic affinities may vary among the different assays.

PROTEIN EPITOPES

Several categories of epitope have been defined for protein antigens, based on the proximity of the relevant amino acids in the primary structure of the protein (Fig. 15.3). The simplest case is the *linear* epitope, where all of the relevant amino acids are derived from a contiguous stretch of the polypeptide chain. However, many – perhaps most – epitopes on globular proteins involve amino acids from two or more stretches of polypeptide that are distant from one another in the primary structure. Such an epitope is referred to as a *conformational*, or *discontinuous*, epitope. In some cases, such as with the capsids of nonenveloped viruses, it is conceivable that a conformational epitope can comprise amino acids derived from

Fig. 15.3 Types of protein epitope. Some antibodies recognize structural features of proteins that arise from the folding of the polypeptide backbone (conformational epitope). Others recognize groups of amino acid residues that are contiguous, or nearly so, in the primary (covalent) structure of the protein (linear epitope). If such a linear determinant is inaccessible in the native structure of the protein, the corresponding antibodies may only be elicited by the denatured form of the protein. Neo-epitopes are created by covalent post-translational modifications, such as proteolytic cleavage. (From Abbas AK, Lichtman AH, Pober JS. Cellular and molecular immunology, 3rd edn. WB Saunders Company, 1997, with permission from Elsevier.)

separate polypeptide chains that are adjacent in the capsid. Another category of protein epitope, the *neo-epitope*, is reserved for those antigenic sites that become recognizable only after a post-translational event, such as proteolytic cleavage. For example, several neo-epitopes have been defined on cleavage products of human C1q, C3, and C9, components of the complement pathway.¹³ Antibodies recognizing such neo-epitopes can be used to monitor the extent of activation of the complement pathway.¹³

Studies in the 1970s on the sizes of epitopes associated with synthetic peptide antigens yielded results suggesting that protein epitopes would maximally involve six or seven amino acids. The first structure of an antibody variable module in complex with a globular protein antigen, determined by X-ray crystallography,¹ indicated that protein epitopes, defined on the basis of intermolecular contact, could be as large as 15–20 amino acids. A similar number of amino acids in the antibody V domains constituted the paratope. Of course, it is possible that there are smaller epitopes on globular proteins, particularly for regions of proteins that protrude or have a high radius of curvature. Peptide antigen–antibody interaction can involve at least 12 peptide amino acids in contact with the antibody.

Antibodies specific for both linear and conformational epitopes have important uses. A synthetic peptide corresponding in amino acid sequence to a segment of the polypeptide chain predicted from the nucleotide sequence can be used to elicit antibodies.¹⁴ In many cases, such antibodies will recognize a linear epitope that is available in a denatured form of the gene product. Therefore, these antibodies can be used to identify the protein following expression and blotting, or electrophoresis and blotting, under denaturing conditions. Antibodies that bind to linear epitopes may recognize a protein in denatured form, but will often not bind to or alter the function of the native protein.

Antibodies with the ability to neutralize protein function generally recognize conformations accessible to the native protein, usually at discontinuous epitopes. However, some antibodies specific for peptides (that correspond in amino acid sequence to a portion of a native protein) or denatured protein cross-react with the protein in a native (folded, functional) state. Such cross-reactivity is more likely to occur when the region being recognized is relatively unstructured in the native structure.¹⁵

CARBOHYDRATE EPITOPES

The classic studies of Elvin Kabat on the binding of antibodies to dextran led to the concept that epitopes on carbohydrate antigens could be as large as six or seven monosaccharide units.¹⁶ However, minimal carbohydrate epitopes can probably be as small as one or two monosaccharides. Even in the case of larger epitopes involving three or more saccharide units, it is typical for the terminal groups to play a dominant role in determining antibody specificity for carbohydrate antigens. Recent studies suggest that, analogous to the conformational epitopes of proteins, polysaccharide epitopes can sometimes result from conformational properties of polysaccharides.

Interactions between antibodies and polysaccharides are typically characterized by relatively low intrinsic affinities compared to antibody–protein interactions.⁵ Two sorts of factor may account for relatively weak antibody–carbohydrate binding: biological constraints related to protection against self-recognition and consequent tissue damage; and physicochemical constraints related to the conformational freedom and high degree of solvation of unbound carbohydrates.

Another important feature of polysaccharide antigens is that they are generally multivalent. Bacterial polysaccharide epitope densities can approach values in the millions per μm^2 , which is probably one to several orders of magnitude greater than the epitope densities for protein determinants on mammalian cells. Therefore, multipoint attachment and functional affinity are likely to be critical factors in the mediation of immunity by anti-polysaccharide antibodies or other carbohydrate-specific proteins.

■ IMMUNE COMPLEXES *IN VIVO* ■

Interactions between antibodies and antigens *in vivo* can result in the formation of molecular aggregates, referred to as *immune complexes*. Deposition of immune complexes in tissues, such as blood vessels, renal glomeruli, renal tubules, the thyroid gland, and the choroid plexus, can result in pathological conditions.¹⁷ Immune complexes can form in the circulation prior to deposition in a given tissue, or they can form directly in the affected tissue. Variables such as concentration, composition, size, charge, and antibody isotype for a given population of immune complexes will influence the magnitude and sites of tissue deposition for those complexes. The magnitude of complement activation and the extent of interaction with Fc and complement receptors, in conjunction with the sites and extent of tissue deposition, determine the biological properties of the complexes. Antigen–antibody lattice size is determined by antigen valence, epitope geometry, antibody valence, the intrinsic affinity of paratope for epitope, antibody and antigen flexibility, the ratio of antibody to antigen, and the absolute concentrations of antibody and antigen. The potential diversity of immune complex morphologies is illustrated in Figure 15.4. These complexes, between a monoclonal antibody specific for a bacterial polysaccharide and various anti-idiotypic or anti-isotypic monoclonal antibodies, are visualized by electron microscopy.

Immune complexes have also been found to have immunoregulatory effects,¹⁸ particularly with respect to antibody responses. Immune complexes can bind simultaneously to B-cell surfaces through antigen (to B-cell surface immunoglobulin), antibody (to Fc receptors), and associated complement components (to complement receptors). The interaction with FcγRIIB, on the B-lymphocyte membrane, has the effect of diminishing the B-cell response. The molecular events underlying these immunoregulatory effects are being intensively studied and have been exploited clinically for many years. Antibody to the erythrocyte Rh antigens is used to prevent immunization of an Rh[−] mother by an Rh⁺ fetus, thereby avoiding hemolytic disease of the newborn in a subsequent Rh⁺ fetus (Chapter 62).

■ CORRELATIONS BETWEEN C_H REGION STRUCTURE AND ANTIBODY FUNCTION ■

Antibodies are heterodimeric proteins that can be functionally divided into variable domains, which bind antigen, and constant domains, which define the effector function of the immunoglobulin. Using these domains, an antibody can physically link a specific antigen to a separate antigen-nonspecific effector molecule, such as a complement component

KEY CONCEPTS

IMMUNE COMPLEXES

- >> Immune complexes are aggregates of antibody and antigen.
- >> Immune complexes can form in tissues or they can form in the circulation and subsequently deposit in tissues.
- >> Immune complexes can activate complement or Fc receptor-bearing cells, leading to tissue damage.
- >> The composition, size, charge, and antibody isotypes characterizing a given population of immune complexes will influence the pathogenic potential of the complexes.

or a cell-bound Fc receptor. Many features of C_H domain structure exhibited by the immunoglobulin isotypes can be understood in the context of this requirement for linkage between antigen and effector molecules.

One property of prime significance for antibody function is intramolecular mobility, often referred to as *segmental flexibility*. Hydrodynamic methods, electron microscopy, X-ray crystallography, and fluorescence polarization have all been used to evaluate the degree of flexibility exhibited by IgG, IgM, IgA, and IgE molecules.¹⁹ In the case of the best-studied isotype, IgG, it is clear that the structural feature most associated with relative motion of one subunit relative to another is the hinge, which connects the C_H1 domain to the C_H2 domain and is encoded by a separate exon.

Immunoglobulin flexibility has important functional consequences to the antibody. First, inter-Fab movements can play an important role in permitting antibodies to bind in monomeric bivalent (or multivalent) fashion to antigenic surfaces that display repetitive epitopes. Second, efficiency in precipitation of multivalent antigen molecules or agglutination of multivalent antigen particles can be correlated with inter-Fab flexibility. And third, optimal interactions of effector molecules with IgG antibody Fc regions has been postulated to depend on the ability of the Fc region to bend out of the plane of the Fab arms (*dislocation*) (but see discussion on complement activation below).

■ FUNCTIONS MEDIATED BY ANTIBODY ALONE ■

Although it is clear that in many *in vivo* situations antibodies mediate their effects with the aid of other molecules and, in selected cases, cells (see next section), there are circumstances where the antibody can influence antigenic targets directly. The very name ‘antibody’ implies the negation of some activity, and antibodies were first defined as factors that could inactivate toxins. Subsequent studies have shown inactivation of viruses, parasites, and enzymes as well.

VIRUS NEUTRALIZATION

A phenomenon of fundamental medical and biological importance is the *neutralization* of viruses by antibodies.²⁰ Although neutralization is defined as the elimination or reduction of the virus’s ability to replicate,

KEY CONCEPTS

STRUCTURE–FUNCTION RELATIONSHIPS
OF C_H DOMAINS

- >> Immunoglobulin function is influenced by differences in quaternary structure and segmental flexibility.
- >> The hinge region helps control segmental flexibility in IgG molecules.
- >> When interacting with multivalent antigens, IgM molecules can adopt a dislocated (staple) configuration in which the Fab arms are bent out of the plane of the Fc regions.

it does not imply a particular mechanism of interference with the process of replication itself. Moreover, the measurement of neutralization can depend on the choice of host cell. In other words, the neutralizing activity of a given antibody for a given virus is not an intrinsic property of the antibody, but is a property of the relationship between antibody and virus, under defined conditions. Consequently, neutralization titers in serum do not always correlate perfectly with protection from infection or disease *in vivo*.

There are several mechanisms by which antibodies may inactivate viruses. Recall that the process by which a virus infects a cell involves multiple steps, including attachment to one or more membrane components, penetration of or fusion with the membrane, uncoating, and genome expression. Although the most obvious mechanism of neutralization is the prevention of viral attachment to the host cell surface, antibodies can block other steps as well. For example, some neutralizing antibodies for enveloped viruses, such as influenza virus, have been shown to prevent fusion between the virion and cell membranes, and some neutralizing antibodies for polio virus have been shown to interfere with viral uncoating in the host cell.

Different isotypes of antibodies may employ different neutralization mechanisms to varying degrees, although this statement should not be interpreted to mean that there is a one-to-one correspondence between isotypes and neutralization mechanisms. IgA, the dominant isotype in mucosal secretions, operates under conditions where complement is less plentiful than in the blood, so virus-specific IgA is more likely to utilize virus-inactivating mechanisms, such as prevention of attachment, without a requirement for complement. In the blood, IgG or IgM antibodies can mediate protection against a virus, either directly in some cases, or with the assistance of complement components in others.

Traditional thinking maintains that antibody mediates any protective effects in the extracellular environment. However, it has been reported that IgA antibodies, being transported by the polymeric immunoglobulin receptor, can mediate protection against intracellular virus.²¹ In viral infections of the central nervous system there is substantial evidence for antibody-mediated clearance by incompletely understood noncytolytic mechanisms.²²

There are several other notable features of antibody–virus interactions. Not all antibodies that bind to molecules on the virion surface will neutralize the virus. For a given virus-encoded gene product, such as the influenza virus hemagglutinin, binding of antibodies to some sites, but

KEY CONCEPTS

VIRUS NEUTRALIZATION

- >> Antibodies can neutralize (decrease the replication of) viruses by several mechanisms, including blocking attachment to the host cell, preventing penetration of the host cell membrane, or interfering with uncoating of the virus within the cell.
- >> Neutralizing antibodies typically recognize proteins or glycoproteins on the virion surface.
- >> Some antibodies that bind to virion surface proteins or glycoproteins are not neutralizing. In some cases such antibodies may contribute to immunity, whereas in others they may actually enhance infection.
- >> The magnitude of neutralization mediated by a given antibody may vary with the host cell used for the measurement.
- >> Neutralization *in vitro* is usually related to protection *in vivo*, but these two properties are not always perfectly correlated.

not others, will effect neutralization. Some gene products on the virion surface may contain no neutralization sites, strictly defined. The neuraminidase of influenza virus may be an example of this category of virion surface protein. However, antibody to influenza neuraminidase, albeit nonneutralizing, is thought to slow the spread of infection by interfering with the escape of progeny virions from an infected cell. Nonneutralizing antibodies, or neutralizing antibodies at suboptimal concentrations, have been found in some instances to enhance the infection of host cells by virus (e.g., HIV-1 or dengue virus). Finally, some nonneutralizing antibodies can mediate protective effects *in vivo*, presumably by engaging antigen-nonspecific effector mechanisms (i.e., complement or Fc receptor-bearing cells) or perhaps through cellular signal transduction.²²

NEUTRALIZATION OF TOXINS AND ENZYMES

In many bacterial infections the clinical consequences of infection are due more to toxic molecules liberated by the bacterial cells than to the presence of the microorganisms themselves. Antibodies to such toxins can provide life-saving protection from disease, despite not directly eliminating the bacteria producing the toxins. The classic example of this situation is infection with *Corynebacterium diphtheriae*, which secretes a potentially lethal exotoxin. Bacteria can also produce additional virulence factors, such as enzymes that facilitate spreading of the pathogen through tissues. Host antibodies that inactivate such enzymes can have a beneficial influence on the clinical course. Inactivation of toxins or enzymes is presumed to result from direct competition between antibody and the target molecule or substrate of the toxin or enzyme, or from the stabilization or induction of conformations that are to some degree incompatible with the normal function(s) of the toxin or enzyme.

In summary, antibodies can use a variety or a combination of mechanisms to play a significant role in protection against both primary infection and reinfection with a diverse array of pathogens, including viruses, bacteria, fungi, and parasites.²³

Electron micrographs (above; $\times 350\,000$) and interpretive diagrams (below) of a mouse IgG₃ mAb

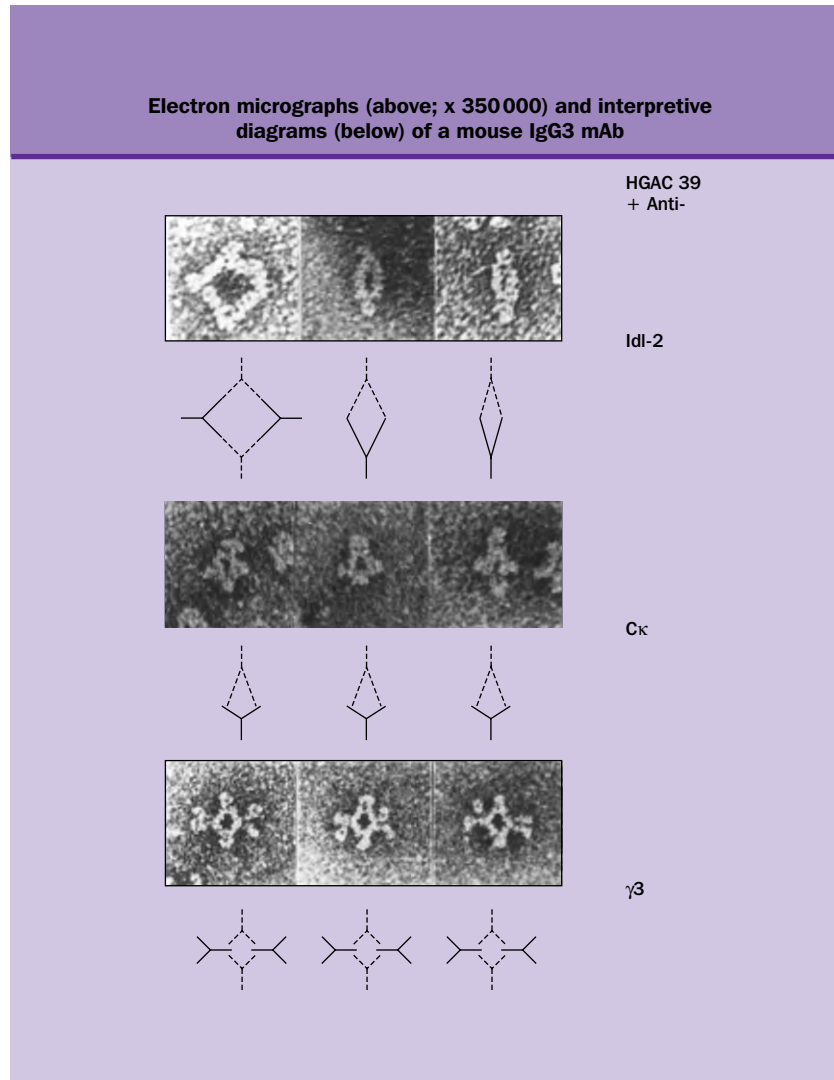

Fig. 15.4 Electron micrographs (above; $\times 350\,000$) and interpretive diagrams (below) of a mouse IgG₃ mAb (HGAC 39; specific for a bacterial polysaccharide) in complex with mAbs specific for, respectively, an idiotope (IdI-2; top), a light chain isotypic determinant (C_κ; middle), and a heavy chain isotypic determinant (γ₃; bottom). The different antibodies are not intrinsically distinguishable in the electron micrographs, but the interpretations take into account information in addition to that provided directly by the electron microscopic images. In the top series of micrographs, the choice of which molecules to represent as solid or dotted figures is arbitrary. (From Greenspan NS. Analyzing immunoglobulin functional anatomy with monoclonal anti-immunoglobulin antibodies. BioTechniques 1989; 7: 1086, with permission from Eaton Publishing Company.)

FUNCTIONS MEDIATED BY ANTIBODY AND ADDITIONAL MOLECULES OR CELLS

COMPLEMENT ACTIVATION

Regardless of whether direct binding of antibody to antigen mediates protective effects, antibody bound *in vivo* will activate antigen-nonspecific effector mechanisms. The exact mechanisms will depend on the

isotype of the antibody as well as on other factors. One critical set of these effector mechanisms is encompassed by the classical pathway of complement activation. The human antibody isotypes vary considerably in their intrinsic ability to activate this pathway. The consensus view is that IgM, IgG₁, and IgG₃ isotypes are effective activators. Whereas some sources state that IgG₂, IgG₄, and IgA are weak or nonactivators of the classical complement pathway, evidence suggests that when epitope density is high, IgG₂ can effectively activate the classical pathway.²⁴ Instead of attempting to decide which subclass is absolutely superior, it is probably more useful to recognize that

complement-fixing ability may not be determined solely by the subclass of an IgG antibody.

One obvious source for the isotype-related variation in complement activating ability is variation in affinity for C1q (IgG₃ > IgG₁ > IgG₂ > IgG₄), the portion of the first component in the classical pathway that physically contacts the C₁H₂ domains of antibodies. The intrinsic affinity of the C1q globular heads for Fc regions of any isotype is relatively low, accounting for the observation that two or more IgG molecules in proximity are required for activation of the classical pathway, beginning with C1. Thus, in the activation of the classical pathway, the functional affinity of C1q for antibody Fc regions is a crucial parameter.

IgG subclass-associated differences in some measures of complement activation have been found, under some experimental conditions, to depend on quantitative differences in steps of the cascade subsequent to the binding of C1q to antibody. Although there has been speculation regarding the role of segmental flexibility in complement activation, there is probably no simple correlation between this physical property and activity in fixing the classical complement pathway.²⁵

Although it is generally agreed that IgA does not activate the classical pathway, its ability to activate the alternative complement pathway has been controversial. Studies with recombinant IgA molecules have suggested that neither IgA₁ nor IgA₂ activates either complement pathway.²⁶

Antibody-mediated activation of the classical complement pathway has a variety of potential consequences, including the creation of additional sites on a foreign particle to which phagocytic cells can attach and ingest the particle (opsonization), and elaboration of substances that mediate leukocyte chemotaxis, additional metabolic changes involved in the destruction of pathogens by leukocytes, and changes in vascular permeability. These inflammation-related processes are described in more detail in Chapter 20. In this scheme, it is the antibody that provides the specificity; the other molecules function similarly regardless of the epitopes involved.

RECEPTORS FOR Fc REGIONS

In addition to the complement system, the other major system with which antibodies interact in the mediation of effector functions is cellular. The specific molecules with which cells recognize antibodies are called Fc receptors (FcR).²⁷ In humans, there are several Fc receptors for IgG (FcγRI, FcγRII, FcγRIII), as well as other Fc receptors for IgA, IgE, and IgM (Fig. 15.5). We will describe selected features of Fc receptors that help to illuminate the principles by which they function.

Some receptors (FcγRI, FcεRI) have relatively high intrinsic affinities for antibody molecules, and can therefore bind significant fractions of monomeric Ig at physiological concentrations. For example, the high-affinity receptor for IgE (FcεRI) binds IgE with an intrinsic affinity of approximately $1 \times 10^{10} \text{ M}^{-1}$. Therefore, even at relatively low concentrations, single IgE molecules can bind to mast cells or basophils through cell surface FcεRI prior to interacting with allergen (antigen). In contrast, FcγRII and FcγRIII have relatively weak intrinsic affinities for IgG Fc regions. Consequently, multivalent forms of IgG, such as are found in complexes of antibody and multivalent antigens (immune complexes), are much more readily bound to these FcR. Thus, for both the complement-dependent and the FcR-dependent effector function pathways, multivalency of Fc regions (functional affinity) plays a critical role.

Several types of functional consequence can follow ligation of FcR by antibody-antigen complexes. These include activation and metabolic alteration of the FcR⁺ cell, phagocytosis of antibody-coated particulate antigens, antibody-dependent cellular cytotoxicity (ADCC), and release of mediators that promote inflammation. These pathways clearly apply to IgG and IgE antibodies. Recent data suggest another possible function that depends on the interaction between antibody (IgA) and a cell surface receptor able to bind to polymeric immunoglobulins (pIgR). Transport of IgA-antigen complexes across epithelial surfaces by pIgR may represent a form of antibody-facilitated antigen excretion.²⁸ In mice, recent studies indicate that the effectiveness of antibodies of the various murine IgG subclasses in mediating FcR-dependent effector functions correlates with the ratio of affinities of antibodies of those subclasses for activating versus inhibiting FcγR.²⁹

ANTIBODIES AS SURROGATE LIGANDS

The notion that one molecule can mimic a second molecule, in one respect or another, is of extraordinarily broad applicability and of profound biological significance. At least three types of mimicry can be distinguished, and each type can be regarded as a continuous (as opposed to discrete) variable.³⁰ First, one can conceive of limited structural mimicry of one molecule by another. By chance, two otherwise different molecules could have regions that happen to contain the same, or similar (in key respects), atoms in the same, or almost the same, three-dimensional arrangement. Second, there is mimicry at the level of non-covalent interaction. In this case, the question of interest is whether the model (object of mimicry) and the mimic bind the same receptor sites and with the same affinities. Third, there is mimicry of more complex biological functions, such as cellular or enzymatic inactivation. It is important to make these distinctions because the extent of mimicry of one type is not a perfect predictor of the extent of mimicry of another type. We have already noted that slight changes in structure sometimes have slight effects on binding affinity or specificity, yet in other cases they have dramatic effects. In other words, structural similarity (mimicry), as we perceive it, is not perfectly correlated with mimicry at the level of binding or the level of elicitation of higher biological function.

KEY CONCEPTS

ANTIBODY EFFECTOR SYSTEMS

- >> Multivalence of Fc regions is often important in activating antibody effector functions.
- >> The occurrence and magnitude of effector function activation varies with antibody isotype.
- >> Effector mechanisms are inherently nonspecific with respect to antigen.
- >> Antibody Fc regions provide the mechanistic link between antigen-specific V domains and antigen-nonspecific effector mechanisms.

Fig. 15.5 Domain structures, binding properties, cellular expression patterns, and functional effects of human Fc receptors. A given FcR may exhibit differences in composition depending on the cell type expressing it. For example, FcγRIII is expressed on neutrophil plasma membranes bearing a glycosylphosphatidylinositol anchor, without Fcγ chains, whereas it is expressed on NK cell plasma membranes as a conventional transmembrane protein in association with Fcγ chains. Similarly, FcγRII-B1 contains an additional stretch of polypeptide encoded by an exon whose product is not represented in the intracellular domain of FcγRII-B2. This additional portion of the polypeptide is believed to prevent the internalization of FcγRII-B1 subsequent to cross-linking.

*A subset of FcγRII-A allotypes bind to human IgG₂.

† For these cells, FcR expression is inducible, not constitutive.

‡ The molecular weight of CD89a chain is 70–100 kDa in eosinophils. (From Janeway CA Jr, Travers P, Walport M, Shlomchik M. Immunobiology: the immune system in health and disease, 6th edn. New York: Garland Science, 2004, with permission from Garland Science.)

There are two aspects of receptor–ligand interaction that antibodies can potentially mimic. First, as noted earlier, the inducibility of a vast repertoire of antibody specificities suggests the potential for identifying, through screening or selection, antibodies that can bind any given target molecule at a given site. Thus, there should be a reasonable probability of obtaining antibodies that bind to a particular receptor at a site bound by some other, perhaps physiological, ligand or co-receptor. The prediction that it should be possible to identify antibodies that can mimic the functional effects of other molecules has been supported by many investigations of anti-idiotypic antibodies and conventional anti-receptor antibodies.^{31, 32}

Second, as noted earlier, the triggering event for many cellular and effector processes in the immune system is the aggregation of receptor molecules by clustered ligands. Therefore, the ability of antibodies, which naturally have a maximal valence of 2 or greater, to cross-link cell surface molecules and initiate signal transduction contributes to the abilities of antibodies to serve as surrogate co-receptors for cell surface molecules. This property of antibodies has greatly facilitated the identification and

functional characterization of many of these molecules, and is also being exploited for therapeutic use.³³

FUNCTIONAL PROPERTIES OF ENGINEERED ANTIBODY MOLECULES

MONOCLONAL ANTIBODIES

Many modern applications of antibodies in research, medicine, veterinary medicine, and other fields rely heavily, although not exclusively, on monoclonal antibodies. By definition, a monoclonal antibody population is derived from a clonal population of B-lineage cells. Therefore, all of the molecules will express identical variable domains and identical antigen specificities. It is the homogeneity of the V domain structure associated with monoclonal antibodies that most

crucially distinguishes them from polyclonal antibodies, such as those conventionally derived from the serum. Homogeneous antibodies give more reproducible and more easily interpreted results for many kinds of assay.

Monoclonal antibodies of selected specificity were first produced by cells referred to as hybridomas.³⁴ In contrast, a myeloma protein would be an example of a monoclonal antibody of unselected specificity. Hybridomas are hybrid transformed cells that are created by the fusion of two types of cell. Each of these parental cells endows the hybridoma with desirable properties. One parent of a hybridoma (the fusion partner) is a transformed cell, usually a myeloma cell line, which contributes a metabolism that supports unlimited growth in tissue culture and high rates of immunoglobulin synthesis and secretion. The myeloma cell lines used as hybridoma fusion partners usually have been genetically manipulated such that they no longer synthesize an immunoglobulin molecule, and they can be selected against in special culture media. The second parental cell is a B lymphocyte, usually from the spleen or lymph node of an immunized animal. This normal B cell provides the genetic information for the production of a particular antibody. Note that the choice of specificity on the part of the investigator is influenced at two stages in the process, including the choice of immunogen and the nature of the screening assay. By screening a population of hybridomas, most of which will secrete different antibodies, with an appropriately designed assay it is possible to identify the minority of cells that secrete a monoclonal antibody of desired specificity.

Monoclonal antibodies are useful for the identification and quantification of diverse molecules of biological or synthetic origin, including human immunoglobulins (e.g., paraproteins), antigens from infectious agents (e.g., HIV p24), hormones, drugs, and toxins. They have also been exploited for therapeutic purposes, such as reversing allograft rejection, killing tumor cells, or preventing cytokine activity contributing to autoimmune disease. The benefits and limitations of monoclonal antibodies for human use are discussed in Chapter 95.

KEY CONCEPTS

MONOCLONAL ANTIBODIES FROM HYBRIDOMAS

- >> Hybridomas are created by fusing normal lymphocytes, typically from animals immunized with an antigen of choice, and transformed cells of B-lymphocyte lineage (myeloma cells).
- >> Monoclonal antibodies produced by a hybridoma are homogeneous, expressing a single amino acid sequence.
- >> Hybridomas can be grown indefinitely in tissue culture or in the peritoneal cavities of syngeneic mice (for murine hybridomas).
- >> Hybridomas can be selected on the basis of the antigenic specificity or functional properties of the monoclonal antibody secreted by the hybridoma.

RECOMBINANT ANTIBODIES

The ability to manipulate the genes that encode antibodies, and thereby manipulate the structures of antibodies, has opened a new era in the study and application of antibodies (Fig. 15.6). Progress has occurred on several fronts. This includes expression of recombinant intact IgG molecules,³⁵ expression of Ig fragments (Fab, Fv) in eukaryotic and

Fig. 15.6 Examples of engineered antibodies and antibody-derived fragments that can be created through the manipulation of antibody genes. Each closed rectangular (constant) or rounded (variable) box represents a domain. The molecule at the bottom of the figure represents a humanized antibody, where the constant domains and variable domain framework regions correspond to human amino acid sequences. Only the hypervariable regions, and in some cases a small number of framework residues, correspond to mouse or rat antibody amino acid sequences. Other structures depicted include an Fab fragment; an Fv fragment; a single-chain Fv fragment (scFv) in which the C terminus of the V_H domain is linked covalently by a linker peptide to the N terminus of the V_L domain; an Fab-enzyme fusion protein; an scFv-toxin fusion protein; an immunoadhesin in which extracellular domains from CD4 have been covalently attached to human heavy chain constant domains; a single V_H domain (dAb); and a peptide derived from a hypervariable region (minimal recognition unit, or mru). Regulatory T cells

Kajsa Wing, Shimon Sakaguchi

16

The normal mammalian immune system protects the individual from a myriad of potentially pathogenic microorganisms while simultaneously avoiding harmful reactions against the normal constituents of the body, i.e., maintaining immunological self-tolerance. The mechanisms that balance active immunity and self-tolerance are of fundamental interest to both basic and clinical immunologists, as the failure of protective immunity risks enhanced susceptibility to infectious diseases and loss of self-tolerance may trigger an autoimmune disorder. Elucidation of these mechanisms holds the promise of permitting manipulation of the immune response to enhance reactivity to self (or quasi-self) antigens, such those expressed on tumor cells, as well as to suppress the immune response to nonself antigens, such as those expressed on organ transplants.

A key feature of the adaptive immune response is that, once triggered, the effector activity against the inciting antigen, self or nonself, is the same. Its purpose is the elimination of the microbe or the destruction of self-tissue. To prevent self-destructive immune responses while permitting protective immune responses to nonself antigens, the mammalian immune system has evolved a series of regulatory mechanisms designed either to inhibit the generation of potentially harmful self-reactive T and

B lymphocytes, termed *central tolerance*, or to downregulate cellular activation and expansion of lymphocytes when they encounter self-antigens, termed *peripheral tolerance*.

For T cells, central tolerance is established in the thymus. During development (Chapter 9), dangerous lymphocytes that carry T-cell receptors (TCR) with high affinity for ubiquitous self-antigens are deleted. This process of *negative selection*, which occurs at an immature stage of thymocyte development, results in the generation of a peripheral T-cell repertoire that is largely self-tolerant. Negative selection is not an absolute process, and some auto-reactive, including potentially pathogenic, T cells escape the net of thymic deletion. Nevertheless, autoimmune diseases occur infrequently, indicating that auto-reactive T cells are somehow controlled in the periphery.

Peripheral mechanisms of self-tolerance include further deletion of self-reactive T cells, the seclusion of self-antigen from T lymphocytes, low TCR affinity, lack of co-stimulation in antigen recognition (*clonal ignorance*), inactivation of auto-reactive T lymphocytes upon encounter with antigen without co-stimulation (*clonal anergy*), and active suppression of self-reactive lymphocytes by other T cells (*dominant suppression*).^{1,2}

This chapter discusses the mechanisms by which regulatory T cells (Tregs), particularly CD4 Tregs, can induce dominant suppression of self-reactive T cells. Several types of T cells with regulatory activity have been described, including subpopulations of $\gamma\delta$ T cells, NKT cells, CD8, and CD4 T cells³ (Table 16.1 and Fig. 16.1). Some of these Tregs are naturally produced in the immune system, while in others the phenotype is induced in naïve T cells as a product of a particular mode of antigen stimulation in a specific cytokine milieu. Although many details of how each of these populations is regulated and how each functions in the normal physiology of the organism remain to be elucidated, the abundance and apparent redundancy of Treg populations is not surprising given the essential need to maintain immune homeostasis and self-tolerance.

Naturally occurring CD4 Tregs have been the subject of the majority of recent Treg studies, which have shed new light on the mechanisms that contribute to a number of immunological disorders. For example, anomalies in natural Treg function or number can be a primary cause of autoimmune disease, allergy, and inflammatory disorders such as inflammatory bowel disease (IBD) in humans. Because of their natural presence

KEY CONCEPTS

IMMUNOLOGICAL SELF-TOLERANCE

Immunological self-tolerance is actively acquired and maintained throughout life by a series of mechanisms that cooperatively and complementarily interact to prevent the maturation and activation of potentially self-reactive lymphocytes.

The mechanisms include:

- >> Clonal deletion
- >> Clonal anergy
- >> Clonal ignorance
- >> Dominant suppression

Table 16.1 Subsets of natural and induced regulatory T cells (Treg)

APC, antigen-presenting cell; DC, dendritic cell; IL-10, interleukin-10; ILT, immunoglobulin transcript; MHC, major histocompatibility complex; NK, natural killer; Th3, T helper 3 cell; TGF-β, transforming growth factor-β; Tr1, regulatory type 1 cell; Treg, regulatory T cell.

in the immune system, CD4 Tregs also provide a tempting target for the treatment and prevention of a number of diseases of immune function.⁴

CD4 REGULATORY T CELLS

CD4 Tregs can be divided into two categories: naturally occurring Tregs and induced Tregs. The so-called naturally occurring Tregs, most commonly referred to as CD25⁺ Tregs because of their constitutive expression of CD25, are generated in the thymus in a functionally mature form. Induced CD4 Tregs, such as interleukin-10 (IL-10)-secreting type 1 regulatory T cells (Tr1) and transforming growth factor (TGF)-β-secreting T helper 3 cells (Th3), differentiate from naïve T cells following antigen stimulation in conjunction with specific conditions in the periphery. Although both natural CD25⁺ Tregs and induced Tregs are suppressive in nature, differences exist in their developmental pathways, phenotype, and function. Thus, these two types of cells are considered to be of separate lineages⁵ (Table 16.1 and Fig. 16.1).

THYMICALLY DERIVED CD4⁺CD25⁺ REGULATORY T CELLS

The first observation indicative of the presence of autoimmune-preventive T cells in the normal immune system and their production by the normal thymus was made more than 30 years ago when thymectomy on day 3 of life (d3Tx) was found to inflict organ-specific autoimmune diseases, such

as oophoritis, in otherwise healthy mice.⁶ Subsequent studies showed that the development of autoimmune disease could be inhibited if the thymectomized animals were reconstituted with CD4⁺CD8⁻ thymocytes or CD4⁺ splenocytes from histocompatible immune-uncompromised animals. In order to pinpoint a specific phenotype for CD4 T cells with regulatory function, surface markers with a more narrow expression pattern were explored. Among these, CD5^{high}, CD45RB^{low}, CD38^{low}, and CD62L^{high} expression was shown to characterize naturally occurring CD4 Tregs in mice.^{3, 7} To date the functionally most useful and specific surface marker of natural Tregs is their high and stable expression of the IL-2 receptor α-chain, CD25. Between 5% and 10% of CD4 T cells express CD25 constitutively in the thymus and periphery of mice, and CD25 expression indeed fits the aforementioned cell surface phenotype of natural Tregs, i.e., CD25⁺CD4⁺ T cells are also largely CD45RB^{low}, CD38^{low}, and CD62L^{high}.⁷ Importantly, transfer of CD4 lymphocytes depleted of CD25⁺ cells induces autoimmunity in athymic nude mice, while co-transfer of CD4⁺CD25⁺ cells protects the mice from disease induction (Fig. 16.2).⁸ Other markers shown to be associated with CD25⁺ Tregs are cytotoxic T-lymphocyte antigen 4 (CTLA-4, CD152) and glucocorticoid-induced tumor necrosis factor receptor protein (GITR). However, neither these nor CD25 can be appreciated as specific markers of natural Tregs since conventional T cells upregulate GITR, as well as CTLA-4 and CD25, after activation.⁹ This dilemma is especially apparent when investigating naturally occurring Tregs in humans where up to 30% of CD4 T cells in peripheral blood express CD25, yet only 2–4% of CD4 T cells, enriched among cells with the highest expression level of CD25 (CD25^{high}), have

Fig. 16.1 Developmental pathways of regulatory T cells (Tregs). Tregs can develop in either the thymus or the periphery and are vital for maintaining tolerance as a counterbalance to effector T cells. Thymically generated Tregs, also known as naturally occurring Tregs or CD4⁺CD25⁺ Tregs, express Foxp3 and develop within the thymus according to a specialized combination of TCR and co-stimulatory signals. Extra thymic development of CD4⁺ Tregs and CD8⁺ Tregs can ensue from a host of different conditions, such as high concentrations of transforming growth factor- β (TGF- β), interleukin-10 (IL-10) or other particular circumstances surrounding antigen priming. The signals that control differentiation of $\gamma\delta$ T cells and NKT cells to cells with regulatory properties are less defined.

suppressive properties.¹⁰ The fact that CD25⁺ Tregs is not a discrete population in humans poses a problem both when obtaining cells for experimental purposes and when evaluating their role in a clinical setting. Therefore, more specific cell surface markers of CD4 natural Tregs need to be discovered. This is an active area of current research with important implications for the future clinical use of Tregs.

THYMICALLY DERIVED CD25⁺ TREGS EXPRESS THE TRANSCRIPTION FACTOR FOXP3

Although functional analysis of Tregs has been hampered by the lack of specific cell surface markers, a major breakthrough was achieved when the transcription factor Foxp3 was found to be specifically expressed by thymically derived natural Tregs and closely linked with their development and function.¹¹ The first hint as to the significance of Foxp3 was given by studies of the Scurfy mutant mouse. This mouse strain suffers from a spontaneous X-linked mutation of the *Foxp3* gene, which leads to fatal lymphoproliferative disease associated with multiorgan infiltrates and early death by 3–4 weeks of age in hemizygous males. Similarly, mutations in the human orthologue *FOXP3* is linked to IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome), which is an X-linked immunodeficiency syndrome associated with organ-specific autoimmune diseases such as type 1 diabetes,

Fig. 16.2 Demonstration of Treg-mediated maintenance of self-tolerance. If a T-cell-deficient mouse receives a transfer of total spleen cells from a normal wild-type mouse of the same strain the recipient remains healthy. However, when CD4⁺CD25⁺ splenocytes are removed prior to transfer the recipient animal develops several types of organ-specific autoimmune disease, such as gastritis, thyroiditis, and type 1 diabetes. This can be prevented if a small number of purified CD4⁺CD25⁺ splenocytes are co-transferred, which shows that CD25⁺ Tregs are present in normal animals and protect from autoimmune disease.

IBD, allergic dermatitis, food allergy, hyperimmunoglobulinemia E, hematological disorders, and severe infections⁴ (Chapter 35). Intriguingly, a common denominator for the conditions observed in mice and humans is deficient levels of CD25⁺ Tregs. Both CD25⁺CD4⁺ T cells and CD25⁺CD4⁺CD8⁻ thymocytes specifically express *Foxp3* mRNA whereas other thymocytes/T cells, T helper 1 (Th), or T helper 2 (Th2) cells scarcely express *Foxp3* even after stimulation.¹¹ Recent analysis of intracellular staining of the Foxp3 protein has shown that, while the majority of Foxp3⁺ cells in mice reside in the CD4⁺CD25⁺ T-cell population, a small fraction can also be found in the CD4⁺CD25⁻ population (Fig. 16.3). Most importantly, retroviral transduction of *Foxp3* in naïve CD25⁻ T cells can convert them to regulatory cells with similar function and phenotype as natural Tregs.¹¹ Broadly, the same pattern of FOXP3 expression can be observed in humans, with most FOXP3⁺ cells among CD4⁺CD25^{bright} cells and a few being CD25⁻ or CD25^{low} (Fig. 16.3). One difference between mice and humans is that human CD8⁺ T cells with suppressive function can, in some cases, express FOXP3. Another disparity is that low levels of FOXP3 seem to be transiently induced by TCR stimulation in nonregulatory T cells derived from peripheral blood; however, this expression is lower than what is seen in CD25^{high}Tregs.⁹ It is likely that Foxp3 may specify the Tregs cell lineage whether Tregs are CD4⁺ or CD8⁺, class II major histocompatibility complex (MHC)- or class I MHC-restricted. Collectively, thymically derived Tregs are best recognized by their expression of Foxp3. Unfortunately, since the Foxp3 protein is present only in the cell nucleus,

CLINICAL RELEVANCE

**IMMUNE DYSREGULATION,
POLYENDOCRINOPATHY, ENTEROPATHY,
X-LINKED SYNDROME (IPEX) IS A RESULT OF
CD25⁺ REGULATORY T-CELL (TREG) DEFICIENCY**

Loss of function mutations of *Foxp3/FOXP3*, an X-linked gene, inhibits the development and function of CD25⁺ Tregs in affected males. Uncontrolled activation/expansion of autoreactive clones creates a lymphoproliferative disease with severe autoimmunity with fatality at an early age. Common symptoms include:

- >> Organ-specific autoimmunity (type 1 diabetes, thyroiditis, hemolytic anemia)
- >> Allergy (dermatitis, hyperimmunoglobulinemia E, food allergy)
- >> Inflammatory bowel disease

it is not useful for the isolation of cells. Thus at present CD25 remains the best and most commonly used marker for the isolation of Tregs.

**DEVELOPMENT AND MAINTENANCE
OF CD25⁺ TREGS**

Several findings point to the thymus as central in the generation of CD25⁺Foxp3⁺ Tregs. First, the phenotype of CD25⁺CD4⁺ thymocytes is very similar to that of peripheral Tregs as they are CD25⁺ and Foxp3⁺. Second, both peripheral and thymic CD25⁺CD4⁺ T cells suppress the proliferation and cytokine production of conventional CD4⁺ or CD8⁺ T cells in a dose-dependent fashion when tested *in vitro*. Third, athymic mice transferred with CD25⁺ T cells spontaneously develop organ-specific autoimmune diseases that can be reversed by co-transfer of either CD25⁺CD4⁺ thymocytes or CD25⁺CD4⁺ splenocytes from normal adult mice.⁴ Therefore, the thymus contributes to self-tolerance by both deleting auto-reactive T cells and producing CD25⁺ Tregs. CD25⁺ Tregs are thought to arise from T-cell clones with relatively high reactivity to self-antigens that are expressed in the thymus. It is as yet unclear as to how these cells are spared from negative selection and how the Tregs developmental pathway, which apparently starts with the induction of Foxp3, is initiated.¹¹ It is nevertheless likely that a higher responsiveness to self-antigen is a benefit when suppressing hazardous auto-reactive T cells, since CD25⁺ Tregs would be more easily and strongly activated when presented with self-antigens in the case of tissue damage. In addition to TCR interaction, it seems that accessory signals, such as co-stimulation through CD28-B7 or CD40-CD40L, play an important role in the production of CD25⁺ Tregs in the thymus, since animals that lack CD28 or CD40 expression generate only minute numbers of Foxp3⁺ T cells in the thymus (Table 16.2).^{4, 12}

In the periphery, the maintenance of CD25⁺ Tregs requires antigenic stimulation, cytokines, and signals from antigen-presenting cells (APCs). It is vital that CD25⁺ Tregs encounter specific antigens to remain in the Tregs pool. For example, cell transfer experiments in d3Tx models have demonstrated that Treg cells from donors of the same sex are better at

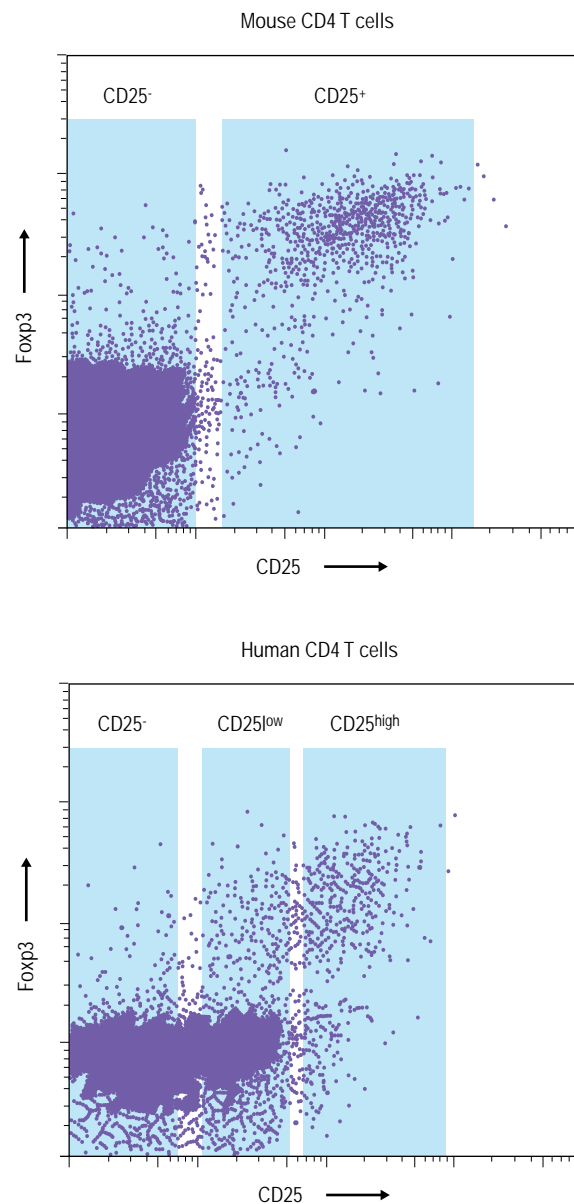

Fig. 16.3 Expression of CD25 and Foxp3 denotes natural regulatory T cells (Tregs) in mice and in humans. In mice, 5–10% of CD4⁺ T cells express CD25 and, among these, almost all are Foxp3⁺. In addition, a few Foxp3-expressing cells reside among CD4⁺CD25⁻ T cells. In the peripheral blood of humans, approximately 30% of CD4⁺ T cells express CD25 but only a fraction of these cells (2–4%) express FOXP3 protein. Although some CD25⁻ T cells are FOXP3⁺, generally, high expression of FOXP3 appears to correlate with high expression of CD25, which in turn represents cells with suppressive function. Foxp3 protein is localized in the nucleus and cannot be used for isolation of viable cells and therefore CD25 expression is exploited to obtain regulatory cells.

Table 16.2 Signals with impact on CD25⁺ regulatory T-cell (Treg) induction, maintenance, and suppression

	Differentiation	Maintenance	Suppressive function
Peptide MHC II interaction	Yes (high affinity)	Yes	Yes at least initially
CD28	Yes (crucial)	Yes (indirectly by induction of IL-2 production in effector T cells)	Not crucial for induction of suppression but high expression on APC breaks suppression
CTLA-4	No	Unclear	Yes (not crucial)
GITR	No	Modest positive effect	Breaks suppression
TLR ligands	No	Yes	TLR ligands initially break suppression but this is followed by induction of enhanced suppression
IL-2	Yes (but not crucial)	Yes (crucial)	High levels break suppression
TGF- β	Not vital for thymic differentiation but may be involved in peripheral induction	Yes	Yes (not crucial)

APC, antigen-presenting cell; CTLA-4, cytotoxic T-lymphocyte antigen 4; GITR, glucocorticoid induced tumor necrosis factor receptor protein; IL-2, interleukin 2; MHC II, major histocompatibility complex II; TGF- β , transforming growth factor- β ; TLR, toll like receptor.

protecting against orchitis or oophoritis than Tregs from donors of the opposite sex, and that Tregs from ovariectomized mice are less competent in preventing oophoritis than those from normal females. Moreover, CD25⁺ Tregs from rats ablated of their thyroid are unable to protect rats from thyroiditis, while the capacity to protect against other organ-specific autoimmune diseases remains unchanged.¹³ In general, CD25⁺ Tregs behave similarly to conventional T cells as they have been shown to recirculate between the blood and lymph and then home to organ-draining lymph nodes where they effectively expand in response to their specific antigen.¹⁴

IL-2 is vital for the maintenance of natural Tregs and CD25 is accordingly not a mere marker for natural Tregs but also a functionally indispensable molecule for them as a key component of the high-affinity IL-2 receptor. Mice genetically deficient in IL-2 or IL-2 receptor α -chain (CD25) or β -chain (CD122) develop a severe lymphoproliferative disease with lymphocyte infiltration in multiple organs, resulting in early death.⁴ Genetic deficiencies of CD25 in humans generate a comparable clinical and pathological pattern. This condition was previously hypothesized to be caused by the failure of IL-2-induced cell death of self-reactive T cells. However, it is now known that IL-2-deficient animals have substantially reduced numbers of Foxp3⁺CD25⁺ T cells, and that disease can be prevented by adoptive transfer of normal CD25⁺ Tregs. Another cytokine that has also proven to be important for the maintenance CD25⁺ Tregs is TGF- β . This cytokine is shown to enhance Treg expression of Foxp3 and render non-Treg cells susceptible to Treg-mediated suppression.^{4,15}

In addition to antigen recognition and cytokines, CD25⁺ Tregs require appropriate interactions with APC for their function and survival. Several molecules of cell adhesion and co-stimulation are important to CD25⁺ Tregs function and homeostasis, including CD18, GITR, CD28, and Toll-like receptors (TLR).⁴ Although CD25⁺ Tregs express these markers and direct signaling takes place through these molecules, indirect effects on Tregs via effector T cells also likely exist and must be taken into

account. For example, CD28 provides naïve T cells with a co-stimulatory signal for promoting IL-2 secretion and preventing cell death. Since CD25⁺ Tregs likely survive on the IL-2 produced by other cells, a lack of CD28 in other T cells and thus their failure to produce IL-2 results in significant reduction of CD25⁺Foxp3⁺Tregs. APCs, in particular dendritic cells (DCs), express TLRs that recognize pathogen-associated molecular patterns shared among microbes or certain self-molecules (e.g., heat shock proteins) released during inflammation. Strong activation of APCs through TLRs instigates DCs to mature and strongly activate and expand both naïve T cells and natural CD25⁺ Tregs. Furthermore, CD25⁺ Tregs express TLR 2, 5 and 8, and stimulation of Tregs through these TLRs may suppress excessive anti-microbial immune responses that could incur immunopathological tissue damage (Table 16.2).⁴

SUPPRESSIVE FUNCTION OF CD25⁺ TREGS

The standard assay to analyze the suppressive function of CD25⁺ Tregs is to co-culture purified cell fractions of T cells with Tregs and then measure the proliferative response upon antigenic stimulation in the presence of APC. Such assays show that freshly isolated CD25⁺ Tregs are not able to suppress T-cell responses *in vitro* unless they are first stimulated via the TCR with a specific antigen. Once activated, they suppress other CD4 and CD8 T cells irrespective of their antigen specificities.¹⁶ CD25⁺ Tregs can inhibit proliferation and cytokine production of naïve T cells, which may be accomplished by downregulation of IL-2 gene transcription. CD25⁺ Tregs can also suppress the function of already differentiated Th1 and Th2 cells *in vitro* and have been shown to reverse ongoing immunopathology like colitis *in vivo*.¹⁵ CD25⁺ Tregs are also able to suppress B cells, NK cells, and NKT cells.¹³

The mechanism behind CD25⁺ Treg-mediated suppression is subject to several different hypotheses that include both soluble and cell surface-bound mediators (Fig. 16.4). *In vitro* studies have shown that CD25⁺

Fig. 16.4 Proposed suppressive mechanisms of CD25⁺ regulatory T cells (Tregs). CD25⁺ Tregs can inhibit many different types of effector cells and can also suppress immune responses at multiple stages, including the initial priming in the lymph node and effector actions at the site of inflammation. The precise mechanism is not known, but numerous theories have been proposed and it would not be surprising if CD25⁺ Tregs suppress by several different mechanisms. *In vivo* Tregs may act in a cell contact-dependent manner by competing directly for stimulatory ligands on the antigen-presenting cell (APC), by absorbing essential growth factors such as interleukin-2 (IL-2), or by directly transmitting an as-yet uncharacterized negative signal to either the T cell or APC. Alternatively, Tregs may use long-range suppressive mechanisms by means of the cytokines IL-10 and transforming growth factor- β (TGF- β).

Tregs need direct cell-to-cell contact with responder cells. Suppression does not occur if Tregs are separated from effector T cells by a semipermeable membrane, even if this allows for the passage of soluble factors.¹⁶ Moreover, CD25⁺ Tregs are not prominent producers of either IL-10 or TGF- β *in vitro*. These features are quite different from Tr1 or Th3 cells, which solely rely on soluble long-range immunosuppressive cytokines, such as IL-10 and TGF- β , for their inhibitory function. Assuming that the mechanism of CD25⁺ Treg-mediated suppression is cell contact-dependent, one plausible theory is that CD25⁺ Tregs compete with effector T cells for stimulatory ligands, regardless of whether these stimulatory ligands are cell surface molecules on APC, such as CD80/CD86, or soluble growth factors, such as IL-2.¹⁷ Other proposed mechanisms involve the transfer of downregulating signals via various molecules expressed on the cell surface of CD25⁺ Tregs. Candidate molecules for this theory include CTLA-4 and surface-bound TGF- β , since blocking the action of either one is shown to abolish suppression. Nevertheless, and to complicate matters further, mice deficient in either TGF- β or CTLA-4 still harbor CD25⁺ Tregs that are functional, at least *in vitro*. Yet another mechanism of suppression is perforin/granzyme B-mediated killing of effector cells by CD25⁺ Tregs, although proof of this mechanism awaits independent confirmation.¹⁷

Despite the fact that immunosuppressive cytokines are redundant for suppression *in vitro*, the *in vivo* situation seems somewhat different. Both TGF- β and IL-10 have been shown to take part in CD25⁺ Treg-mediated suppression of IBD in mice.⁷ Curiously, adoptive transfer of IL-10-deficient CD25⁺ Tregs failed to protect against colitis, although it could inhibit the development of gastritis.¹⁷ One important difference between gastritis and IBD is the presence of intestinal bacteria, which, together with the local cytokine environment, is likely to affect the way tolerance is mediated.

Several pieces of evidence suggest that CD25⁺ Tregs can interact with APC, especially DC, and through them inhibit immune responses. Current models of DC-mediated tolerance propose that T-cell antigen recognition on immature DCs is tolerizing, while recognition on mature DCs drives effector responses. In the steady state (e.g., in the absence of infection or trauma) DCs capture various auto-antigens, as well as inhaled or ingested proteins, and then migrate to the lymph node while still in an immature state. In the lymph nodes, naïve T cells will then encounter antigen and receive a suboptimal signal of activation, which is thought to drive their differentiation towards a Treg rather than an effector T-cell phenotype. On the other hand, if the same antigen is presented under different conditions in the presence of so-called “danger signals” (pro-inflammatory cytokines, microbial products), then DCs will mature fully and upregulate co-stimulatory and MHC molecules, and will initiate production of pro-inflammatory cytokines, leading to an effector T-cell response. APCs cultured with CD25⁺ Tregs downregulate CD80/86 and become impaired in their ability to stimulate T cells. Additionally, CD25⁺ Tregs can elicit the induction of the enzyme indoleamine dioxygenase (IDO) by ligation of CTLA-4 with CD80/86 on a particular class of DCs.¹⁷ The induced IDO catalyzes the amino acid tryptophan to the metabolite kynurenine, which has negative effects on T-cell responses. Indeed, new techniques (e.g., two-photon laser-scanning microscopy) that allow for *in vivo* study antigen priming in the lymph node have shown that, while the contact between CD25⁺ Tregs and effector T cells is limited, stable interactions exist between CD25⁺ Tregs and DC during ongoing suppression.¹⁴

Overall, little is known about the mechanisms of suppression *in vivo* and it remains unclear whether cell contact-dependent mechanisms are involved. Nevertheless, it appears that more than one suppressive mechanism can be utilized by CD25⁺ Tregs, depending on the intensity of the immune response, the site of regulation, and the cytokine milieu.¹⁷

PERIPHERALLY INDUCED CD4⁺ REGULATORY T CELLS

In addition to thymus-derived natural CD25⁺CD4⁺ Tregs, there is abundant evidence supporting the peripheral development of T cells with suppressive properties and an anergic phenotype. For example, Foxp3-expressing CD25⁺CD4⁺ Tregs, functionally and phenotypically similar to natural Tregs, can be induced from naïve T cells by *in vitro* antigenic stimulation in the presence of high-dose TGF- β or by specific ways of *in vivo* antigenic stimulation, e.g., targeting of antigen to immature DC or chronic low-dose antigen administration.⁹ The physiological significance of these Treg induction pathways remains to be determined. Other induced Tregs include TGF- β -secreting Th3 cells and IL-10-secreting Tr1 cells, which have been shown to be present and

functional in humans following bone marrow transplantation and in response to allergens (Table 16.1).

Tr1 cells were initially generated *in vitro* from CD4 T cells rendered anergic by chronic stimulation in the presence of IL-10, which is a potent negative regulator of inflammation and lymphoproliferation.¹⁸ T cells obtained in such a fashion produce a unique pattern of cytokines distinct from Th1 or Th2 cells, with IL-10 as the signature cytokine. Tr1 cells secrete some TGF- β , interferon- γ , and IL-5, but no IL-4 or IL-2. Tr1 cells are anergic but can proliferate in the presence of IL-2. Currently there is no specific surface marker for Tr1 cells and their identification relies on the IL-10 they produce that, together with TGF- β , forms the basis for their suppressive function. Notably, Tr1 cells do not express high constitutive levels of CD25, nor do they express Foxp3, which clearly separates them from CD25⁺ Tregs. Besides *in vitro* induction of Tr1 cells with IL-10 and antigen, CD4 T cells can differentiate into Tr1 cells when stimulated by APCs. This may more closely mimic what takes place *in vivo*. Antigenic stimulation with immature DCs (i.e., low levels of co-stimulatory molecules), or DCs pre-treated with IL-10/TGF- β , confers naïve CD4 T cells with an anergic and suppressive phenotype both *in vitro* and *in vivo*.¹⁸

Tr1 cells can participate in the induction of tolerance in humans, as well. For example, the presence of Tr1 cells can be correlated with lack of graft-versus-host disease in bone marrow transplantation. Similarly, Tr1 cells can be induced following specific immunotherapy in allergic patients. Tr1 cells specific for *Escherichia coli* proteins can be isolated from the intestinal mucosa of healthy donors. In pemphigus vulgaris, which is an autoimmune disorder with circulating autoantibodies against desmoglein-3 (Chapter 63), Tr1 cells specific for desmoglein-3 can be isolated from pemphigus vulgaris-prone but apparently healthy individuals, while pemphigus patients rarely have such cells. Collectively, Tr1 cells can be induced to auto-antigens as well as foreign antigens as a component of the mechanisms that maintain tolerance to both self and nonself.¹⁸

Th3 cells were identified in mice during investigations of the mechanisms of oral tolerance. Oral tolerance has presumably evolved to prevent hypersensitivity reactions to food and microbial antigens present in the mucosal flora. It was found that mice fed with myelin basic protein, a neuronal auto-antigen, developed T cells that preferentially produced TGF- β together with varying amounts of IL-4 and IL-10. These T cells had suppressive properties, mediated by TGF- β , and could prevent the induction of experimental autoimmune encephalomyelitis, the murine equivalent of multiple sclerosis (MS) (Chapter 65). There are currently no surface markers for Th3 cells but they can be generated *in vitro* when grown in the presence of TGF- β , IL-4, and IL-10. Since the intestinal mucosa has high basal levels of all these cytokines, which are upregulated after antigen administration, it is conceivable that this particular environment drives the formation of Th3 cells while a different setting may produce Tregs of another phenotype.¹⁹

■ OTHER SUBSETS OF REGULATORY T CELLS ■

Immunosuppressive T cells other than CD4 Tregs have been identified. They can recognize antigens that differ from those typically presented to CD4 T cells via MHC class II and thus can serve to induce tolerance in other settings. One example is CD8 T cells with TCRs that recognize

THERAPEUTIC PRINCIPLES

ADJUSTMENT OF THE IMMUNE RESPONSE BY CD25⁺ REGULATORY T CELLS (TREG)

Reduction of CD25⁺ Treg suppression, or reducing Treg numbers:

- Enhancement of tumor immunity
- Clearance of infections
- Improvement of responses to vaccines

Boost of CD25⁺ Treg function or increasing Treg numbers:

- Treatment of autoimmunity
- Treatment of allergic responses
- Induction of transplantation tolerance

Control of immunopathology due to excessive responses to foreign antigens (i.e., pathogens)

antigen presented by the MHC class Ib Qa-1 molecule (HLA-E in humans). Qa-1 has limited polymorphisms, is expressed solely by activated T cells, and can present both foreign and self-peptides. For example, Qa-1 peptide complexes on CD4 T cells can bind the inhibitory CD94–NKG2 receptor complex on CD8 T cells. This is believed to be one way that Qa-1-restricted CD8 T cells regulate T-cell responses.²⁰ CD8⁺CD28[−] Tregs suppress immune responses by direct interaction with APCs. These cells can be generated *in vitro* by multiple rounds of stimulation with alloantigen. They can downregulate co-stimulatory molecules or upregulate the inhibitory immunoglobulin-like transcript 3 (ILT3) and ILT4 receptors on DCs, leading to impaired activation of effector T cells.²¹

In mice, $\gamma\delta$ T cells with a regulatory phenotype exist as a subset of epithelial $\gamma\delta$ T cells. Mice deficient in $\gamma\delta$ T cells do not appropriately regulate responses to various pathogens. $\gamma\delta$ T-cell-deficient mice show accelerated autoimmune responses in models of systemic lupus erythematosus and spontaneously develop dermatitis when bred on certain genetic backgrounds. Commonly, these conditions are driven by $\alpha\beta$ T cells and the $\gamma\delta$ T cells function by locally inhibiting $\alpha\beta$ T cells. Since humans lack an equivalent population of intraepithelial $\gamma\delta$ T cells, it is plausible that this immune regulation can be provided by other types of suppressive cells.²²

NKT cells respond to the nonclassical class I antigen-presenting molecule CD1d, which binds glycolipids rather than peptides. NKT cells can induce either pro-inflammatory (interferon- γ) or anti-inflammatory (IL-4, IL-10, IL-13) immune responses. The prerequisites for this choice remain ill defined. Nevertheless, under appropriate conditions NKT cells can clearly promote tolerance, as illustrated in studies of transplantation and oral tolerance (Table 16.1).²³

■ CLINICAL RELEVANCE OF REGULATORY T CELLS ■

Natural Tregs are key controllers of physiological and pathological immune responses including self-tolerance. This makes them suitable targets for immunotherapy (Tables 16.1 and 16.3).

Table 16.3 Potential therapeutic approaches for regulatory T-cell (Treg)-based therapy

AUTOIMMUNITY

Natural CD25⁺CD4⁺ Tregs are engaged in active suppression of autoimmune disease. Depletion of natural Tregs leads to the development of autoimmune disease in rodents. Abnormal Treg development or function can be a direct cause of autoimmune disease in humans, as exemplified by IPEX.⁴ Decreased levels of CD4⁺CD25^{high} T cells in peripheral blood have been reported in systemic lupus erythematosus, psoriatic arthritis, and autoimmune liver disease. On the other hand, studies of MS and type 1 diabetes have not detected differences in Treg numbers between patients and controls and conflicting data have been reported in rheumatoid arthritis (RA) with regard to both function and numbers of CD25^{high} Tregs. A general observation is that CD25⁺ Tregs increase in number at the site of inflammation.²⁴ In the case of RA, synovial fluid from patients with ongoing RA was found to contain increased numbers of CD25⁺ Tregs as compared to CD25⁺ Tregs levels in peripheral blood. Functional assessment of CD25⁺ Tregs from inflamed synovium in RA reveals increased suppressive properties of these cells, although this enhanced suppressive function of Tregs is apparently not enough to halt the inflammatory process. In contrast, CD25⁺ Tregs obtained from the blood of MS patients have been reported to demonstrate a decreased ability to suppress proliferation of effector T cells. Thus, reduced levels of CD25⁺ Tregs in peripheral blood are not a general finding in autoimmune disease, may not necessarily reflect the actual conditions at the site of inflammation, and may or may not play a causative role in common autoimmune diseases.²⁴

ALLERGIC DISEASE

CD25⁺ natural Tregs play an important role in suppressing the development of allergic reactions to innocuous environmental substances. This is best illustrated by IPEX, which is accompanied by not only organ-specific autoimmune diseases but also severe dermatitis, high levels of serum immunoglobulin E and sometimes eosinophilia.⁴ Indeed, CD25⁺ Tregs from the blood of healthy nonallergic donors suppress both proliferation and production of Th2 cytokines when challenged with specific allergens *in vitro*. When the same experiment is performed with Tregs from allergic individuals, they fail to downregulate Th2-related responses to allergens. Since the suppressive ability for polyclonal

stimuli is retained in allergic patients, this deficiency appears to be directly related to the allergen to which the individual has been sensitized. Thus the failure of Tregs to suppress the response to the allergen probably does not reflect a general deficiency, but one specific to that allergen. The inability to suppress Th2 responses induced by birch or grass pollen is aggravated when the allergic reaction is ongoing and effector cells are fully activated, as during spring and summer compared to wintertime. Addition of IL-4 can attenuate the CD25⁺ Tregs-mediated suppression of Th2 clones *in vitro* in the same way as IL-2, which may provide an explanation for the insufficient control of ongoing allergic responses by Tregs.¹³ It has been found that both nonallergic and allergic individuals harbor allergen-specific IL-4-producing effector T cells, IL-10-producing Tr1 cells, and CD25⁺ Tregs, but in different proportions. Thus, the balance between Th2 and certain Tregs populations may dictate whether clinical allergy will develop. Indeed, in the setting of curative specific allergy immunotherapy, allergen-specific, IL-10-producing T cells can be induced. Furthermore, children who grow out of their cow's-milk allergy have higher numbers of CD4⁺CD25⁺ T cells specific for β -lactoglobulin compared to children with clinically active allergy. This suggests that certain allergies can be cured by extrathymic induction/expansion of antigen-specific Tregs and that the balance of Tregs versus effector T cells is of importance to prevent allergy.^{13, 25}

TRANSPLANTATION

An ultimate goal of organ transplantation is to establish tolerance to allogeneic organ grafts as effectively and stably as to self-tissues, but without the need for continuous general immunosuppression.²⁶ Needless to say, Tregs have sparked a lot of attention in this area of research. CD25⁺ Tregs were first shown to suppress graft-versus-host disease (GvHD) in murine models of allogeneic bone marrow transplantation. Similarly, nude mice transplanted with allogeneic skin rejected the graft when reconstituted with CD4⁺CD25⁻ T cells alone, but retained the graft when large enough numbers of CD25⁺ Tregs were co-transferred. In humans, attempts have been made to prevent GvHD in bone marrow transplantation and induce graft tolerance in organ transplantation by the use of purified CD25⁺ Tregs.²⁷ Efforts have also been made to expand donor-specific Tregs *ex vivo* to enhance suppression and lower the number of Tregs needed for tolerance induction. Other means to

establish tolerance to grafts are by administration of monoclonal antibodies to various cell surface molecules such as CD4, CD8, and CD40L on T cells and CD40, CD80/86 on APC or CD11a and CD54 expressed by both T cells and APC.²⁶ These treatments may more potently suppress the activation and expansion of effector T cells than that of CD25⁺ natural Tregs, and thus allow the latter to expand in a graft-specific fashion and tip the scale in favor of dominant tolerance. In addition, such monoclonal antibody treatments may induce Tregs of extrathymic origin. Indeed, several types of inducible Tregs including CD8⁺ Tregs and Tr1 are shown to contribute to graft tolerance.^{18, 21}

A third potential way to promote the induction of Tregs in organ transplantation is to evaluate the effects of various immunosuppressants in terms of altering the balance between Tregs and effector T cells. Different immunosuppressants target different pathways in cell metabolism and can therefore have different effects on cell populations that behave in dissimilar ways, such as effector T cells and Tregs. Dosage and timing of administration, as well as specific drug combinations, seem to be a promising angle of transplantation immunotherapy with the purpose of inducing graft tolerance and preventing graft rejection. Tregs have been shown to home to, and reside within, the graft, which is stably accepted once a dominance of Tregs has become established. Treg-mediated transplantation tolerance is not a systemic phenomenon but rather localized to the graft, and as such it would not incur the dangers that accompany general immunosuppression.²⁶

TUMOR IMMUNITY

It is now well known that many of the tumor-associated antigens recognized by a patient's T cells are normal self-constituents, indicating that anti-tumor immune responses are within the range of CD25⁺ Treg control. Therefore, the presence of natural Tregs in the normal immune system may not only prevent autoimmunity but also hamper immune surveillance of cancer.²⁸ In fact, CD25⁺ Tregs are shown to reside in the tumor mass, where they likely block any immune response targeting malignant cells. For example, the frequency of CD25⁺ Tregs is increased in tumors of metastatic melanoma or cancers in the pancreas and lung. Moreover, high levels of CD25⁺ Tregs in the tumor are correlated with a poor prognosis and survival. Whether the elevated levels are due to migration of Tregs into the tumor or to an expansion on the site is not clear, but evidence exists in support of both events. For example, ovarian tumor cells and infiltrating macrophages secrete the Treg-recruiting chemokine CCL22 and, in addition, many tumors produce TGF- β , which contributes to the maintenance of CD25⁺ Tregs and may also induce Foxp3 expression in non-Tregs cells within the tumor microenvironment. It is now evident that both effector T cells and Tregs have to be assessed in monitoring the efficacy of anti-cancer immunotherapy.²⁸

Involvement of Tregs in tumor immunity indicates that anti-tumor immune responses can be provoked or enhanced by depleting Tregs in a host that is otherwise responding poorly. Experimental mouse models have indeed demonstrated that simple depletion of CD25⁺ Tregs with anti-CD25 antibody results in tumor eradication, and similar effects can be achieved with *in vivo* administration of anti-GITR or anti-CTLA-4 antibodies.²⁹ Depletion of CD25⁺ T cells also enhances the effect of vaccination with tumor antigens. Pharmacological agents are another possible way of altering the effector T cell/Tregs ratio. For example, fludarabin was shown to selectively decrease the frequency of CD25⁺ Tregs in patients receiving chemotherapy. Conversely, previously used

regimens, such as administration of exogenous IL-2, are now being re-evaluated, since IL-2 may expand Tregs. As expected from the role of Tregs in self-tolerance, a caveat of Treg-based therapies of cancer is the possible development of autoimmunity, which may very well depend on the degree and period of *in vivo* systemic Tregs depletion as well as the genetic makeup of the host.²⁸

INFECTIOUS DISEASE

Immune responses to infectious agents, such as bacteria and viruses, often result in tissue damage, which might be more severe if it were not for the involvement of Tregs. On the downside, in many cases Tregs may contribute to the development of chronic infections. As previously discussed, CD25⁺ Tregs have the potential to respond directly to microbial products and are believed to suppress responses to infectious agents. A number of studies show that the outcome of an infection partly hinges on the proper balance between effector T cells and Tregs.³⁰ A well-documented example is the murine model of colitis, where effector T cells in the absence of Tregs are triggered by the commensal bacteria to cause intestinal inflammation in immunodeficient hosts, while co-transfer of CD25⁺ Tregs protects the animals through an IL-10-dependent mechanism.⁷ Adoptive transfer of CD25⁺ Tregs prevents lethal pneumonia in T-cell-deficient mice infected with *Pneumocystis jirovecii* (formerly *P. carinii*), but at the expense of a deficient protective response and microbial clearance. Similarly, CD25⁺ Tregs suppress Th1 responses in mice infected with *Helicobacter pylori*, thereby limiting the mucosal inflammation, but resulting in a higher bacterial load. Human studies show that CD25⁺ Tregs from carriers of *H. pylori* suppress responses to *H. pylori* antigens *in vitro* and have increased frequencies of CD25^{high} T cells in both the stomach and the duodenal mucosa compared with healthy controls. Additionally, the number of CD25⁺ Tregs in the circulation inversely correlates with liver damage in human hepatitis C virus infection. Taken together, modulation of the infectious response by Tregs can limit tissue damage but may enhance pathogen survival.

This sort of compromise may not always be adverse to the host. For example, in murine *Leishmania major* infection, CD25⁺ Tregs prevents complete eradication of the parasites, which results in the persistence of low numbers of microbes that have proved to be essential for the development of T-cell memory and prevention of re-infection. However, this delicate balance can be tipped in favor of the pathogen, which can be seen in the case of malaria and various viral infections, such as human immunodeficiency virus (HIV). For example, HIV-specific CD4 and CD8 T-cell responses are substantially suppressed by CD25⁺ Tregs *in vitro* in most HIV-infected individuals. Taken together, future treatments, as well as vaccines, will have to take Tregs into account and, depending on the pathogen in question, it might be necessary to reduce or enhance the activity of Tregs to achieve a favorable outcome (Table 16.3).³⁰

Helper T-cell subsets and control of the inflammatory response

Todd N. Eagar, Stephen D. Miller

17

T cells play a critical role in regulating the body's defenses against pathogenic nonself. In order for T cells to participate in inflammatory processes, they must become activated, expand in number, differentiate, travel to sites of inflammation, and carry out effector functions. A substantial fraction of T cells expresses the CD4 co-receptor on the cell surface (Chapter 4), which helps stabilize the interaction between their T-cell receptors (TCR) and class II major histocompatibility complex (MHC) molecules bearing cognate antigen (Chapters 5–7). T cells expressing CD4 provide help, direction, and effector function to the immune response as well as contributing to the antigen specificity of the interaction and promoting the development of memory. This chapter focuses on the generation and function of this helper T-cell subset during inflammatory processes.

INITIATING IMMUNE RESPONSES

Inflammation is a fundamental process that the body uses in response to infection and tissue injury. Inflammation manifests with *calor* (heat), *rubor* (redness), *tumor* (swelling), and *dolor* (pain). These cardinal signs are initiated nonspecifically at the site of infection or trauma. They result from the initial release of chemical mediators that enhance vascular permeability and promote the recruitment of immune cells. Cells of the innate immune system (Chapter 3), such as granulocytes and monocytes, are rapidly recruited from the blood into the site of inflammation. Tissue-resident macrophages and dendritic cells migrate to the site from adjacent tissues. Immunosurveillance proceeds both locally and in the draining lymphoid tissues. The cells of the innate immune system use cell surface receptors, such as the Toll-like family of receptors (TLRs), to scan local tissues for the presence of infectious agents. TLRs and other innate receptors recognize conserved pathogen-associated molecular patterns (PAMPs) that are expressed by offending microbes. The detection of these molecular signals of infection leads to the rapid recruitment of additional cells and direct enhancement of the inflammatory process. Phagocytes and tissue dendritic cells act to clear damaged tissue and cell debris from the inflammatory site. Following phagocytosis, the dendritic cells traverse into the lymphatic vessels and migrate to the regional

lymph nodes. In these lymph nodes, they present peptide antigens taken up at the site of tissue damage to resident T cells. Antigen presentation in the lymph nodes permits induction of an appropriate T-cell immune response against the antigens detected at the site of inflammation. These interactions between T cells and dendritic cells are critical for the activation, expansion, and differentiation of the T cell, which are required processes for the initiation of T-cell-mediated inflammation (Fig. 17.1).

CD4 T-cell activation activity can lead to self damage and even overt autoimmunity. For this reason, T-cell activation is a tightly regulated process that requires multiple stimuli. Naïve T cells exist in a quiescent state and are incapable of participating in inflammatory processes. The primary signal required for T-cell activation is an antigen-specific

KEY CONCEPTS

T-CELL-MEDIATED INFLAMMATION REQUIRES ACTIVATED OR MEMORY T CELLS

Naïve T cells

- >> Traffic through spleen and lymph nodes
- >> Require professional antigen-presenting cells
- >> Require strong co-stimulation
- >> Delayed expansion
- >> Delayed cytokine production

Activated T cells

- >> Traffic through most tissues
- >> Respond to antigen presented by nonprofessional antigen-presenting cells
- >> Require less co-stimulation
- >> Rapidly expand following antigen encounter
- >> Rapidly produce effector cytokines

Fig. 17.1 T-cell expansion and differentiation. Following emigration from the thymus, CD4 T cells travel through the lymph nodes. Inflammation results in the recruitment of tissue dendritic cells (DCs) into the draining lymph nodes. In the lymph nodes, DCs present antigen to naïve T cells. Effective antigen presentation stimulates the activation, proliferation, and differentiation of T cells into Th1, Th2, Th17, or uncommitted T central memory (Tcm) cells.

interaction between the TCR and a self MHC molecule bearing a cognate peptide (Chapters 5, 6, and 13).

Each T cell possesses a TCR created by DNA recombination in the thymus (Chapter 4) that bears specificity for peptide epitopes presented in the context of peptide bound to self MHC. This requirement that the T cell interact with self MHC on the surface of an antigen-presenting cell (APC), such as a mature dendritic cell, provides a level of control beyond that experienced by B lymphocytes, which can interact directly with cell-free antigens in solution. The trimolecular TCR–peptide–MHC interaction permits the APC to help shape the T-cell response by providing additional information to the T cell. This information is the product of two types of interaction provided by the APC – adhesion and co-stimulation. Both types of interactions are necessary for optimal T-cell activation.

The affinity and avidity of TCR and MHC/peptide are insufficient for the T cell to maintain stable contact with an APC. However, engagement of the TCR promotes signals that activate tight adhesion between the T cell and APC by means of molecules such as the integrin LFA-1 (CD11a) binding to ICAM (CD54). Firm adhesion promoted by integrin–ICAM interactions permits a T cell to interact with an APC for up to 20 hours. These long-term interactions are necessary¹ for full activation of naïve T cells because they permit formation of the structured signaling complex known as an immunological synapse.

The immunological synapse consists of the TCR, its signaling components, and accessory or co-stimulatory molecules.² These co-stimulatory molecules provide an additional level of control of T-cell activation by allowing the APC to provide information about the source of the antigen. For example, dendritic cell expression of the B7 molecules, CD80 and CD86, which are ligands for the co-stimulatory receptor CD28, increases following TLR signaling. This provides the T cell with the information that the peptide it has recognized is likely to be the product of a microbial infection. Ligand of co-stimulatory molecules such as CD28 provides additional activating stimuli to the T cell and thus lowers the threshold for full activation.

Co-stimulatory molecules possess structured intracellular domains that interact with components of several intracellular signaling pathways. When properly engaged, the combination of TCR–MHC/peptide, integrin/ICAM adhesion, and co-stimulatory receptor signals triggers a series of intracellular biochemical signaling pathways whose combined effect leads to the activation of the T cell. In the presence of incomplete stimulation, i.e., if co-stimulation is lacking, T cells are prevented from participating in inflammation and may become unresponsive to further stimulation (anergy) or undergo a process of programmed cell death (apoptosis). This important safety mechanism is used to prevent inappropriate activation of T cells and helps maintain T-cell peripheral self-tolerance (Chapter 13).

Due to the critical role played by the APC in this process, T-cell activation is critically tied to the activation state of the dendritic cell. Immature dendritic cells are incapable of stimulating functional T-cell responses. Immature dendritic cells may become mature through TLR stimulation. TLR stimulation leads to increased expression of MHC class II, B7-1, B7-2, CD40 and inflammatory cytokines, all of which play a key role in permitting the mature dendritic cells to stimulate T-cell activation. This is exemplified by the result of the interaction between CD40 on the APC and its ligand CD154, whose expression by the T cell is induced following TCR signaling. Signals transduced through CD40 internally in the APC lead to the upregulation of MHC class II–peptide complexes and the ligands for co-stimulatory molecules such as B7-1 (CD80) and B7-2 (CD86). Together the enhanced expression of MHC/peptide and B7 family molecules increases the ability of the APC to stimulate other T cells. This process is known as *licensing* and is one of the methods by which CD4 T cells can act through APCs to help CD8 T-cell responses.³

T-CELL EXPANSION

Although T-cell activation can be detected within 8 hours of exposure to antigen, days will pass before T-cell immune responses can be detected from a naïve host. This delay is partially due to the need to generate sufficient numbers of T cells to produce a detectable and effective response. It has been estimated that the frequency of T cells specific for any given antigen is approximately one per 1×10^6 total CD4 T cells.⁴ By this measure, the total number of T cells recognizing a single peptide epitope can be estimated at around 100 cells per mouse or 10^5 per human. These estimates are corroborated by experimental evidence in CD8 T cells, demonstrating that a naïve mouse possesses 100–200 CD4 T lymphocytes (CTLs) reactive against a single epitope.⁵ Given this low initial frequency of T cells specific for a given epitope, T cells must go through several rounds of division to achieve sufficient numbers to mount an effective response.

Cellular proliferation following antigen exposure begins slowly, taking up to 2 days for the first divisions to occur in the lymph nodes and spleen. Peak expansion occurs around 7 days after antigen exposure. Many of the activated T cells will have undergone six or more rounds of cell division, a process known as clonal expansion. With six rounds of cell division, the original T cell can yield up to 64 daughter cells, each of which possesses the same TCR and thus the same specificity for antigen. Clonal expansion thus permits a rapid net increase in antigen-reactive T cells in the draining lymph node. To appreciate the full scope of the T-cell response against an infectious agent, it is important to realize that T-cell responses can be generated against multiple epitopes derived from multiple antigens present in that agent. Expansion of T cells specific for each epitope of each antigen permits generation of a very large number of T cells specific for the inciting pathogen. This expanded population of T cells does not persist. Following expansion, there is a period of T-cell loss from the lymph nodes. This loss of T-cell numbers is due to a combination of cell death and migration from the lymph nodes to tissues.

TRAFFICKING

Several key differences exist between naïve (resting) and activated T cells that influence their ability to participate in inflammatory processes. Among these differences is the ability of activated T cells to migrate to tissue sites and carry out effector functions. As discussed in greater detail in Chapter 12, T-cell migration relies upon three basic types of interactions between the T cell and the vascular endothelium. The first step is a rolling process mediated by the interaction of selectin molecules (L, E, or P) with their ligands. Selectins slow the T cell and allow close contact with the endothelial cell glycocalyx. The second step is mediated by chemokines (Chapter 11). Binding of chemokines to their receptors on the T cell leads to rapid G protein-coupled signaling, calcium flux, and activation of integrins. The integrins arrest T-cell movement on the luminal side of the blood vessel by stimulating strong adhesion to the endothelial cell. This sets the stage for subsequent transmigration of the T cell across the vessel wall and into the surrounding tissues.⁶

Naïve T cells and effector T cells traffic through different sets of tissues. This differential trafficking is due to varied expression of selectins, chemokine receptors, and integrins by the T cells and endothelial cells. Naïve T cells circulate almost exclusively through the lymphatic system. Following thymic maturation and export from the thymus to peripheral lymphoid tissue, naïve T cells recirculate from the blood into lymph nodes and then travel through the lymphatic ducts back into the circulation. This pattern of movement relies upon the expression of L-selectin or CD62L. L-selectin expression allows adherence to the high endothelial venules (HEV) found in the cortex of lymph nodes. Within hours of being activated by antigen, T cells downregulate expression of L-selectin and upregulate expression of ligands for E and P selectin. The change in selectin/ligand expression allows the activated T cells to interact with endothelium at sites distal from the lymph node in a tissue-specific manner. For example, while entry into the lymph nodes is mediated by L-selectin, entry into skin requires ligands for E-selectin and entry into the lung requires ligands for P-selectin.⁶

Naïve and activated T cells express different patterns of chemokine receptors and therefore follow different gradients. For example, naïve T cells expressing CCR7 follow gradients of CCL21 (SLC) as they migrate through the HEV and into T-cell-rich areas of the lymph nodes,

Peyer's patches, and spleen. This promotes the retention of naïve T cells in lymphoid tissues, where they undergo initial activation. Upon activation, T cells express a new set of chemokine receptors that allow them to traffic in the periphery, but they now respond poorly to SLC. In contrast, activated T cells respond to chemokines such as CCL3 (MIP-1 α).

Recent studies have shown that damage within specific tissues can influence the attraction of T cells by means of different chemokine gradients. For example, expression of CCR4 appears to assist in the homing of T cells to the skin, while other chemokine receptors are used by activated T cells trafficking to other areas. There also appears to be a temporal regulation of chemokine expression during ongoing inflammation. In a murine model of central nervous system autoimmunity, relapsing experimental autoimmune encephalomyelitis, different chemokines are expressed in the spinal cord at different stages of the immune response. This suggests a model for recruitment of T cells of different specificities, as well as monocytes, which are intimately involved in the tissue damage.⁷

Another level of control of tissue-specific migration is exerted by the integrins. Naïve T cells express predominantly LFA-1 ($\alpha_L\beta_2$, CD11a, CD18). LFA-1 interacts with ICAM-1 (CD54) and ICAM-2 (CD102). Interactions between LFA-1 and ICAM-1 are essential for extravasation into the lymph nodes of naïve T cells, as well as memory T cells and B cells. Migration to the Peyer's patches requires $\alpha_4\beta_7$ integrin in addition to LFA-1. Following activation, LFA-1 expression is markedly increased, as is the expression of other integrins. The importance of differential integrin expression is manifest as more is learned about their role in migration into specific tissues. VLA-4 ($\alpha_4\beta_1$, CD49d) is important for migration into a variety of sites, including the central nervous system and the lungs. Additional molecules other than the integrins are important in migration into the tissue. One of these, CD44, is expressed rapidly following T-cell activation. CD44 has been shown to play a role in T-cell rolling and is also important for extravasation of T cells from the vessels.

Activated T cells can traffic through many tissues. Selectivity is provided at the level of the tissue by expressing narrow subsets of selectin ligands, integrin ligands, and chemokines. The exact role of this specificity is not fully understood. Taken together, the differences in receptors and ligands expressed in naïve versus activated T cells can account for the differences in T-cell trafficking observed between these populations.^{6, 8}

DIFFERENTIATION OF CD4 TH SUBSETS

Following activation, CD4 T cells have the potential to differentiate into three general categories of cell types based on function: those possessing pro-inflammatory effector characteristics, those possessing regulatory/anti-inflammatory activities, and those functioning as memory cells (Fig. 17.1). The end result of this differentiation process ultimately dictates what type of immune response will be produced.

CD4 T cells function by producing cytokines. The idea that T helper cells could be divided into subpopulations that produced a distinct set of cytokines and a specific set of effector functions was discovered through study of long-term murine CD4 T-helper cell clones and cell lines.⁹ It was observed that, after repeated, long-term stimulation, CD4 T-cell clones would produce two distinct patterns of cytokines. Based on the cytokine expression phenotype of the cells, the

KEY CONCEPTS

CD4 EFFECTOR PHENOTYPES

Th1

- >> Produce interferon (IFN)- γ , interleukin (IL)-2, tumor necrosis factor (TNF)- α and TNF- β (LT- α)
- >> Stimulate immunoglobulin (Ig)G₂ and IgG₃ class switching
- >> Responses mediated by macrophage activity
- >> Promote phagocytic activity via:
 - Antibody-mediated Fc γ RIII cross-linking
 - Antibody-mediated complement deposition
 - Antibody-mediated opsonization
 - IFN- γ -mediated macrophage activation

Th2

- >> Produce IL-4, IL-5, IL-6, and IL-10
- >> Stimulate IgG4 and IgE class switching
- >> Responses mediated by mast cells and eosinophils
- >> Increase degranulation through:
 - Fc ϵ R1 cross-linking
 - IL-5-mediated eosinophil activation

Th17

- >> Produce IL-6, IL-17, and TNF- α
- >> Activate local endothelium
- >> Induce cytokine and chemokine production
- >> Increase infiltration by neutrophils
- >> Activate cell-mediated inflammation

two subsets were given the designation T helper 1 (Th1) and T helper 2 (Th2). Further study demonstrated additional CD4 T-cell phenotypes, each of which possesses its own distinct set of effector and regulatory capacities. In addition to Th1 and Th2, Th17, Tr1, adaptive regulatory T cells (Treg), central memory, and effector memory cell phenotypes have been identified.

CD4 EFFECTOR CELL PHENOTYPES

CD4 T effector cells are those that promote inflammatory processes through the release of cytokines. These cells function by modifying or promoting the activity of accessory cells, which ultimately mediate the inflammatory processes required for clearance of the antigen. Effector CD4 T cells are divided into three basic groups: Th1, Th2, and Th17. Cells belonging to these subsets are recruited and activated at sites of inflammation (Fig. 17.2) where they can be distinguished by their cytokine production profiles (Table 17.1).

Th1 cells are classically defined by the production of granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon (IFN)- γ , interleukin (IL)-2 and LT (tumor necrosis factor (TNF)- β). The Th1

Fig. 17.2 Generalized model for Th₁ and Th₂ mediated inflammation. Top left: introduction of an infectious agent stimulates the release of chemokines and tumor necrosis factor (TNF)- α from tissue macrophages stimulating the recruitment (upward arrows) of T cells and monocytes through the local vasculature. Antigen recognition by Th₁ cells stimulates the local production of Th₁ cytokines. Interferon (IFN)- γ activates macrophages, enhancing the clearance of infectious agents. Top right: trafficking to sites of Th₂ responses is stimulated by local chemokine expression leading to T-cell recruitment. Antigen recognition leads to interleukin (IL)-4 production by Th₂ cells which stimulates B-cell immunoglobulin E (IgE) class switching. Production of IL-5 activates eosinophils. Cross-linking of Fc ϵ R1 molecules bound to IgE leads to the degranulation of mast cells (Ma) and eosinophils (E). Bottom: recruitment of Th17 cells and restimulation by antigen result in the release of IL-6, IL-17, and TNF- α , which promote the recruitment, activation, and function of many cells, particularly neutrophils.

phenotype is elicited by the innate immune response to infection by intracellular bacteria, fungi, and viruses. Infection with these pathogens activates TLR signaling and the subsequent production by dendritic cells and NK cells of cytokines critical for Th1 development.

Th1 differentiation is promoted by IL-12, IL-18, IL-27, IFN- γ , and type 1 interferons. It is inhibited by IL-4 and IL-10. IL-12 production is critically associated with dendritic cell activation and is thought to be the critical factor associated with Th1 commitment. IL-18 plays a dual role in Th1 function by promoting Th1 commitment and eliciting IFN- γ production by fully differentiated Th1 cells. IL-27 is also produced by dendritic cells and is associated with Th1 commitment. Th1 differentiation is further enhanced by exposure to IFN- γ . A variety of cells such as NK cells and previously committed Th1 cells are thought to be important early sources of IFN- γ . The binding of IFN- γ to the IFN- γ receptor activates Stat1 signaling, which in turn stimulates the production of the Th1-restricted transcription factor Tbet. Tbet serves to reinforce the Th1 phenotype by promoting IFN- γ and IL-12R β_2 expression.¹⁰

Th1 cells help activate macrophages, natural killer (NK) cells, B cells, and CD8 T cells, thereby function in promoting cell-mediated

Table 17.1 T-helper cell effector function through cytokine secretion

Th1	
IL-2	T-cell growth and potentiation of Fas-mediated apoptosis NK cell growth and cytolytic activity B-cell growth and antibody production
IFN- γ	Increases MHC class I and class II expression on numerous cell types Promotes Th1 differentiation Macrophage activation, stimulates phagocytic killing and oxidative bursts Induces IgG ₂ α and IgG ₃ class switching Inhibits IgG ₁ and IgE class switching Inhibits Th2 proliferation Activates neutrophils Activates endothelium to promote CD4 T-cell adhesion Stimulates NK cell cytolytic activity Required for the activation of CD8 CTLs
TNF- α	Activates vascular endothelial cells, enhancing leukocyte recruitment Activates neutrophils, eosinophils, and macrophages Stimulates IL-1, IL-6, TNF, and chemokine expression by macrophages Protects against viral infections, similar to IFNs Increases MHC class I expression Induces fever Activates coagulation
LT (TNF- β)	Activates neutrophils and osteoclasts Activates vascular endothelial cells, enhancing leukocyte recruitment Cytotoxic activity against tumor cells Stimulates adhesion molecule expression Increases MHC class I expression
Th2	
IL-4	Growth and differentiation of Th2 cells B-cell growth and MHC class II upregulation Induces IgG ₁ class switching (IgG ₄ in humans) and IgE Inhibits IgG _{2a} and IgG ₃ class switching Mast cell growth Inhibits macrophage activation Induces VCAM expression on endothelium – recruits eosinophils/monocytes
IL-5	B-cell growth and activation Eosinophil differentiation Eosinophil activation and survival
IL-10	Inhibits cytokine and chemokine production in monocytes, especially TNF, IL-1, and IL-12 Inhibits macrophage activation and function Inhibits T-cell-mediated inflammation
IL-13	Induces IgG ₁ class switching (IgG ₄ in humans) Upregulates MHC class II on monocytes and B cells Inhibits proinflammatory cytokine production by monocytes B-cell co-stimulation Induces IgG ₁ class switching (IgG ₄ in humans) and IgE Increases MHC class I expression
Th17	
IL-6	Activation of acute phase response inducing fever and antibacterial responses Stimulation of CRA and SAA production in liver Promotes Th2 and Th17 differentiation Activation and elicitation of NK responses Promotes plasma cell differentiation and Ig production
IL-17	Increase T-cell proliferation Promote neutrophil recruitment and activity Promote cytokine production, including IL-6 and TNF- α Induce chemokine production
TNF- α	See above
IFN, interferon; Ig, immunoglobulin; IL, interleukin; MHC, major histocompatibility complex; NK, natural killer; TNF, tumor necrosis factor	

inflammatory responses. Macrophage function is regulated at several levels. GM-CSF promotes the production of monocyte lineage cells from the bone marrow, thereby increasing the pool of macrophage precursors. IFN- γ enhances macrophage microbicidal activity by initiating nitric oxide (NO) production via iNOS, upregulating production of oxygen radicals, and increasing phagocytic function. IFN- γ also promotes antigen presentation by upregulating macrophage MHC class I, MHC class II, and co-stimulatory molecule expression. In mice, IFN- γ can activate NK cells and also mediate humoral responses by acting on B cells to mediate antibody class switching to an IgG_{2a} isotype.¹¹ IgG_{2a} activates the classical complement pathway and can bind Fc γ receptors expressed on phagocytic cells, thereby promoting opsonization. Lastly, IFN- γ acts in conjunction with another Th1 cytokine, IL-2, to promote the differentiation of CD8 T cells into cytotoxic effector cells. Macrophage-dependent Th1-mediated inflammatory responses are known as *delayed-type hypersensitivity* (DTH) responses. *In vivo*, DTH responses are critical for protection from intracellular pathogens, including bacteria, fungi, and viruses. Th1 cells have also been implicated in the pathogenesis of many autoimmune diseases, such as multiple sclerosis, type 1 diabetes mellitus, rheumatoid arthritis, and Crohn's disease.

Th2 cells are defined by their production of IL-4, IL-5, IL-9, IL-10, and IL-13. Naïve T cells express the IL-4 receptor (IL-4R). *In vitro*, the critical step in Th2 cell differentiation is the presence of exogenous IL-4 and the absence of IFN- γ during T-cell activation. *In vivo* Th2 differentiation is thought to require IL-4 produced by basophils, eosinophils, mast cells, NKT cells, or even previously differentiated Th2 cells. The combination of TCR (NFAT), co-stimulatory (CD28 and ICOS), and IL-4R/STAT6 signaling promotes IL-4 transcription and the production of the transcription factors c-Maf and GATA3. c-Maf functions to promote IL-4 production and suppress IFN- γ , thereby helping to establish Th2 polarity. GATA3 appears to contribute to Th2 differentiation by inhibiting IFN- γ while promoting IL-5 and IL-13 production (Fig. 17.3).¹⁰

Th2 cells release IL-4 and IL-5, which then attract and activate eosinophils and mast cells. Th2-type cytokines promote class switching to IgG₁, IgE, and sIgA in mice, or IgG₄ and IgE in humans. Antigen triggering of IgE bound to Fc ϵ R1 receptors on eosinophils or mast cells leads to the release of inflammatory factors such as histamine, platelet-activating factor, prostaglandins, and leukotrienes (Fig. 17.2). These factors act on the local environment, producing vascular dilation and leakage, bronchial constriction, and intestinal hypermotility. Anaphylaxis can be produced on a systemic level. These eosinophil and mast cell-dependent reactions are known as *immediate-type hypersensitivity* (ITH). ITH responses are important for ridding the body of intestinal helminthes (Chapter 29). In fact, components of helminth eggs strongly promote Th2 differentiation. Th2 responses are also associated with atopy and hyper-responsive airway conditions, such as asthma (Chapter 40) and allergies (Chapters 42–44).

Recently, a third type of CD4 helper T cell has been identified. Th17 CD4 T cells are characterized by the production of IL-17, TNF- α , and IL-6. Differentiation towards the Th17 phenotype appears to require the presence of IL-6, IL-23, and TGF- β , and the absence of type 1 interferons, IFN- γ and IL-4 (Fig. 17.3). Much of the Th17 cell potency can be attributed to the production of IL-17. Other sources of IL-17 are neutrophils, CD8 T cells, and $\gamma\delta$ T cells. IL-17 is a potent promoter of inflammation, particularly with regard to cellular recruitment. IL-17 induces the expression of adhesion molecules and the production of the pro-inflammatory mediators IL-6, G-CSF, several chemokines,

Fig. 17.3 Factors influencing T-effector differentiation. Cytokine exposure during the activation stage of naïve T cells strongly influences T-effector differentiation. Depicted here are the factors promoting and inhibiting Th1. (Top) Th2, (middle) and Th17 (bottom) differentiation following functional activation of undifferentiated T cells.

prostaglandin E₂, and matrix metalloproteinases (Fig. 17.2). The effect of Th17 cells on recruitment is further enhanced by the production of TNF- α . Evidence from experimental models suggest that IL-17 plays a critical role in host defense against *Klebsiella pneumoniae* and in models of autoimmune diseases, including collagen-induced arthritis and experimental autoimmune encephalomyelitis.¹² In many ways, Th17 cells appear to be potent cell-mediated effectors with similarities to Th1 cells.

REGULATORY T CELLS

The idea that T cells may possess the ability to suppress or regulate the function of others is not a new one. Our understanding of regulatory function by T cells was greatly enhanced by the discovery of CD25 as a marker for a regulatory subpopulation of CD4 T cells. This has led to a deeper understanding of Treg cells (Chapter 16) and their function in the immune system.

The majority of CD4⁺, CD25⁺, FoxP3⁺ Treg cells (natural Treg) are thought to develop regulatory ability in the thymus. A separate

population, known as adaptive Treg cells, has been found to develop in the periphery. Once differentiated, adaptive Treg cells are similar in phenotype to natural Tregs in that they express CD4, CD25, CD38, CD62L, CD103, and FoxP3. Although not fully characterized, adaptive Tregs are thought to be generated in the periphery in response to a widely expressed antigen, through prolonged exposure to antigen, or as a result of polyclonal stimuli. Differentiation to become an adaptive Treg may therefore result from antigen presentation by poor APCs such as immature dendritic cells or other nonprofessional APCs. Stimulation in the presence of inhibitory cytokines such as IL-10 and TGF- β also appears to favor adaptive Treg differentiation. Similar to natural Tregs, adaptive Treg cells are capable of suppressing CD4 and CD8 T-cell responses both *in vitro* and *in vivo*. Unlike natural Tregs which function in a cell contact-dependent manner, adaptive Tregs appear to act at least in part through the secretion of IL-10 and TGF- β . These cytokines may regulate effector T cells directly or indirectly by inhibiting dendritic cell activity. The generation of adaptive Tregs is of great interest as a cell-based therapy for inflammatory diseases, including autoimmunity.¹³

Tr1 cells have been defined as a population of CD4 T cells that produce IL-10 in response to stimulation. Unlike adaptive Tregs, Tr1 cells do not express FoxP3, nor do they necessarily express CD25. Tr1 cells are produced *in vivo* following antigen delivery to or infection of the respiratory system. It is thought that antigen exposure in the presence of IL-10 and TGF- β , which are normally found in the lungs, is important for Tr1 differentiation. Experimentally, Tr1 cells can be induced by repeated intranasal antigen delivery.¹⁴ In fact, it has also been found that Tr1 cells are induced during the course of infection by *Bordetella pertussis*.¹⁵ Tr1 cells produce IL-10, which blocks proliferation of naïve T cells, prevents Th1 differentiation by blocking IL-12 production, and enhances differentiation of T cells toward a Tr1 phenotype.

MEMORY T CELLS

A critical contribution of adaptive immune cells to host defenses is the generation of immunological memory. Following an immune response, small numbers of T cells persist long-term and are called memory T cells. Memory T cells function to protect the host from re-infection by the same microorganisms. The level of protection correlates with the number of specific memory cells present in the host. Creation of a memory T-cell population is a critical component of T-cell-dependent vaccination strategies.

There are several reasons why memory cells are uniquely capable of accelerating responses against repeat antigen. First, memory cells are maintained at higher frequencies than naïve cells. Second, memory T cells proliferate and produce cytokines in response to stimulation with lower doses of antigen, less co-stimulation, and much faster kinetics than do naïve cells. Third, memory cells enhance and promote APC function and secrete polarizing cytokines, such as IFN- γ or IL-4. Finally, they accelerate the activity of naïve T cells.

Memory T cells can be divided into two general subgroups based on their patterns of migration. Central memory cells are T cells that have re-expressed the secondary lymphoid homing receptors CCR7 and L-selectin following activation. Expression of CCR7 and L-selectin allows the central memory T cells to recirculate through the secondary lymphatic organs similar to naïve T cells. Lymph node circulation is benefi-

cial because dendritic cells from diverse tissue sites continuously bring antigen to the draining lymph nodes, thereby increasing the effective area of memory cell surveillance.

Effector memory T cells express homing receptors similar to activated T cells. This not only prevents effector memory cells from trafficking through the lymph nodes, but allows the effector memory T cells to migrate through the peripheral tissues, either through uninflamed tissues or in response to localized inflammatory stimuli. Memory cell responses are thus bolstered through the process of immune surveillance at distinct sites. Differentiation to become central or effector memory cells might be through distinct mechanisms. Central memory cells develop from T cells that have failed to proliferate fully or differentiate to a specific Th phenotype.¹⁶ These central memory cells can differentiate during subsequent antigen encounters. On the other hand, effector memory cells are thought to differentiate from previously committed T cells and retain their effector characteristics.

GENERAL CONSIDERATIONS IN EFFECTOR T-CELL DIFFERENTIATION

Several key concepts of T helper differentiation are important with regard to the cellular differentiation of CD4 T cells. First and foremost, all effector, regulatory, and memory T cells are thought to arise from naïve thymic emigrant precursors. This supposition was confirmed when it was shown that T cells from TCR transgenic mice differentiate into effector, regulatory, and memory phenotypes even though they possess the same TCR. Second, differentiation to a specific phenotype is self-promoting on the one hand and inhibitory to other phenotypes on the other (Fig. 17.3). Both promotion and inhibition result from the production of subset-specific effector cytokines. For example, IFN- γ production early in Th1 differentiation promotes signaling through the IFN- γ R, triggering STAT1 signals which then promote IL-12R expression and inhibit IL-4R expression. Similarly, IL-4 expression promotes Th2 differentiation while also inhibiting responsiveness to IL-12 and IFN- γ . By regulating gene expression and chromatin remodeling, critical transcription factors such as Tbet (Th1) or Gata3 (Th2) reinforce commitment of one T-helper phenotype in lieu of the others. Third, commitment to a given Th phenotype has proven irreversible under normal conditions. That is, a fully committed Th cell cannot redifferentiate towards an alternative phenotype (Fig. 17.4). For example, Th1 cells cannot express Th2 cytokines even when they are cultured for extended periods in Th2-skewing conditions. Only by forced expression of Gata3 or Tbet can Th1 or Th2 clones change their Th phenotype.¹⁰ Fourth, *in vitro* or *in vivo*, differentiation can be incomplete. The presence of undifferentiated precursor cells or central memory cells can adopt different Th phenotypes upon subsequent antigen stimulation (Fig. 17.4).

CLINICAL EXAMPLES OF EFFECTOR CD4 T-CELL FUNCTION

Human Th1 and Th2 populations were first described in T-helper cell clones stimulated by purified protein derivative (PPD) of *Mycobacterium tuberculosis* and *Toxocara canis* antigens, respectively. The majority of

Fig. 17.4 Mechanism of Th phenotype shift. Under appropriate conditions, T-cell activation may result in daughter cells adopting one of several T-effector phenotypes. Within a polarized population of Th cells, a subset of undifferentiated T lymphocytes may exist (here referred to in the general category as Tcm). Upon restimulation, fully committed Th1, Th2, or Th17 cells will produce Th1, Th2, or Th17 phenotypes, respectively. Tcm or other uncommitted cell types retain the potential to differentiate into T effectors of any phenotype, depending on the context of the secondary stimulation.

M. tuberculosis-specific T-cell clones produced IL-2, IFN- γ , and TNF- β , while the helminth-specific Th2-type cells made IL-4 and IL-5.¹⁷ Th1 and Th2 responses have subsequently been described in human infections and diseases. Th17 cells have been detected in humans but their function has not been well characterized. IL-17 has been isolated from human CD4 T cells and has been associated with inflammatory responses in asthma, multiple sclerosis, psoriasis, rheumatoid arthritis, and transplant rejection.¹⁸ Table 17.2 summarizes responses to selected pathogens in which Th1 and Th2 effector responses have been indicated.

The Th1 and Th2 paradigm is not limited to infectious agents. Th1-type T cells can be isolated from the cerebrospinal fluid and peripheral blood of patients with multiple sclerosis, a T-cell-mediated autoimmune demyelinating disorder.^{19, 20} These findings have been supported by results from experimental autoimmune encephalomyelitis (EAE), a rodent model of multiple sclerosis. Mouse and rat models of EAE show that Th1 cells play an important role in EAE. In these models, myelin-reactive CD4 T cells isolated from diseased animals produce primarily Th1 cytokines. Th1 cells play an important role in the initiation and continuation of disease. There is also evidence that recovery from EAE is associated with an increase in the presence of IL-10²¹ and IL-4-producing cells.²²

■ TERMINATION OF T-CELL RESPONSES ■

Termination of inflammatory immune responses and return to homeostasis requires a sharp decrease in both T-cell numbers and T-cell activity. Failure to return to pre-inflammation T-cell numbers

■ KEY CONCEPTS

REGULATION OF T-CELL RESPONSES

- >> Cell death pathways
Tumor necrosis factor (TNF) family receptors: Fas/FasL, Trail and TNFR1
Potentiated by interleukin-2 (IL-2)
- >> Inhibitory receptor activity
CTLA-4 and PD1
Inhibition of T-cell receptor (TCR) signaling
- >> Cytokine-mediated regulation
Anti-inflammatory cytokine production (IL-10, transforming growth factor (TGF)- β)
Cytokines that promote and inhibit inflammation at different stages of a response (interferon- γ , IL-2, IL-27)
Regulation of apoptosis (IL-2, TNF- α)

and activity would be predicted to have several adverse consequences. First, with each succeeding infection, the body would be increasingly burdened by the energy requirements of maintaining larger T-cell numbers. Second, there would be a loss of TCR diversity resulting from the overrepresentation of clonally expanded T cells. Third, there is an increased risk of damage to self by the presence of large numbers of activated effector T cells, which are easily retriggered. The termination of T-cell responses and restoration of homeostasis result not only from the loss of the original stimulus, but from several active control processes, including the induction of cell death, activation of inhibitory signaling pathways, and cytokine production. These processes lead to the elimination of large numbers of effector T cells and to modulation of the function of the other surviving clones.

■ CELL DEATH PATHWAYS ACTIVE IN T-CELL HOMEOSTASIS ■

Several cell death pathways are important in the restoration of homeostasis. Deletion of peripheral T cells following an immune response has been attributed primarily to the interactions of Fas (CD95) and Fas ligand (FasL), which promotes apoptosis. Following activation, T cells upregulate the surface expression of Fas and FasL. T cells are sensitized to Fas-mediated apoptosis by either exogenous stimulation from another cell (death signal) or by stimulation from endogenous molecules (suicide signal). This process is known as *activation-induced cell death* (AICD). Mutations in Fas and FasL lead to the accumulation of activated lymphocytes in the periphery, a human condition known as ALPS (Chapter 14). Another TNF-family member, TRAIL, has also been associated with AICD. Mice genetically deficient in TRAIL show enhanced susceptibility to autoimmune disease. The evidence suggests that TRAIL primarily regulates AICD in Th2 cells.²³

Table 17.2 T-cell effector responses to selected pathogens.

Organism	Nature of the immune response
Bacteria <i>Borrelia burgdorferi</i> <i>Chlamydia trachomatis</i> <i>Helicobacter pylori</i> <i>Legionella pneumophila</i> <i>Listeria monocytogenes</i> <i>Mycobacterium leprae</i> <i>Mycobacterium tuberculosis</i> <i>Treponema pallidum</i> <i>Yersinia pestis</i>	Th1 responses associated with protection and joint pathology Th1 responses protective and source of pathology Th1 responses involved in ulcer formation Th1 responses associated with immunity Th1 responses are protective: interferon- γ from $\gamma\delta$ and CD8 T cells is important Severity and phenotype of disease depends on Th1 and Th2 predominance Th1 responses control infection Th1 resolves infection, Th2 chronic Th1 responses associated with immunity
Fungi <i>Aspergillus fumigatus</i> <i>Blastomyces dermatitidis</i> <i>Candida albicans</i> <i>Cryptococcus neoformans</i> <i>Paracoccidioides brasiliensis</i>	Th2 production predominates: does Th1 offer protection? Th1 protects: Th2 switch in progressive disease Th1 responses are protective Susceptibility associated with Th2 response Th1 response associated with protection Infection stimulates Th2 response, but Th1 response protects
Parasites <i>Leishmania spp.</i> <i>Filaria</i> <i>Schistosoma mansoni</i> <i>Trypanisoma cruzi</i> <i>Giardia lamblia</i>	Th1 responses are protective Th2 responses allow chronic infection Initiates Th2 production Th1 response appears protective Th1 and humoral responses protect Th2 responses are typically directed against eggs Th1 responses inhibit parasite replication, but protection is not completely CD4-dependent Th1 and Th2 responses protect
Viruses <i>Measles</i> <i>Hepatitis B</i> <i>Human immunodeficiency virus</i> <i>Respiratory syncytial virus</i>	Th1 responses are protective Th1 responses seen in spontaneous recovering patients Shift from Th1 to a Th0 (Th2?) response late in disease correlates with susceptibility to pathogens Th1 response protects, Th2 response kills

ACTION OF INHIBITORY RECEPTORS

T cells express several Ig-family transmembrane proteins containing immune tyrosine inhibitory motifs (ITIMs). Two of these, CTLA-4 and PD-1, are expressed on peripheral T cells following activation and play an important role in terminating T-cell responses *in vivo*. CTLA-4 binds to CD80 and CD86, thereby sharing ligands with the positive co-stimulatory molecule CD28. CTLA-4 engagement inhibits T-cell function by competing with CD28 for available ligand and inhibiting proximal TCR signaling through its association with the phosphatases SHP-2 and PP2A. Underscoring the importance of CTLA-4 in T-cell homeostasis, mice that are genetically deficient in CTLA-4 develop a severe CD28-dependent lymphoproliferative disease, tissue infiltration,

and early death.²⁴ PD-1 interacts with two ligands, PDL1 and PDL2, which have different expression patterns throughout the immune system and peripheral tissues. Like CTLA-4, engagement of PD-1 limits T-cell cytokine production and proliferation. PD1 signals may also enhance T-cell apoptosis. Loss of PD-1 has been associated with autoimmune cardiomyopathy, arthritis, and a lupus-like glomerulonephritis disease.²⁵

CYTOKINE-MEDIATED INHIBITION

Another method of controlling T-cell activity is through cytokine signaling. Cytokines (Chapter 10) terminate immune responses by loss or withdrawal of growth factors, by direct anti-inflammatory properties, and

by promoting apoptosis, or programmed cell death (Chapter 14). In the early stages of an immune response, IL-2 functions as a growth factor by promoting T-cell survival and expansion. IL-2 and its receptors are rapidly expressed by CD4 T cells upon activation. Loss of IL-2 signals through decreased production or loss of receptor expression deprives the cell of survival signals and leads to AICD. IL-7 is another growth factor important for the survival of activated and memory T cells. Loss of IL-7 or IL-7 receptor results in increased apoptosis among activated and memory T-cell populations.²⁶

Cytokines can also limit T-cell responses directly. Apart from its role in Th1 inflammation and macrophage activation, IFN- γ downregulates CD4 T-cell responses. Mice deficient in IFN- γ or IFN- γ R show heightened T-cell responses. IL-10 inhibits macrophage activation, downregulating chemokine production and thus diminishing T-cell responses by suppressing co-stimulatory molecule expression by APCs. IL-10 is produced by Th2, adaptive Tregs, and Tr1 cells as well as by monocytes and macrophages. IL-10-deficient mice develop inflammatory bowel disease due to dysregulated Th1 responses. A role for IL-27 in downregulating T-cell responses has recently been described. Mice genetically deficient for the IL-27 receptor develop exaggerated CD4 T-cell responses and inflammatory diseases. These effects of IL-27 can be attributed to its role in suppressing Th1 responses and CD4 T-cell proliferation.²⁷ TGF- β_1 is an anti-inflammatory cytokine that is produced by subsets of regulatory T cells as well as by a variety of other cell types throughout the body. Unlike IL-10, which targets APCs, TGF- β_1 directly inhibits T-cell proliferation. Mice deficient in TGF- β_1 have multitissue infiltration of activated lymphocytes and macrophages. Interestingly, IL-2 signaling has also been identified to play a positive role in the termination of T-cell responses by promoting the activity of regulatory T cells. Tregs

express high levels of IL-2R and require constant IL-2 signals for survival.

Cytokines can also quell T-cell responses by promoting apoptosis. TNF- α is well characterized as possessing pro-apoptotic function. TNFR1 possesses a death domain and binding of TNF- α results in the activation of the caspase pathway and apoptosis. In addition to its role as a growth factor, IL-2 can enhance FAS-dependent apoptosis.²⁸

THERAPEUTIC REGULATION OF IMMUNE RESPONSES

Inflammation is the method used to respond to foreign antigen and rid the body of unwanted microorganisms. Uncontrolled inflammation, however, is the source of tissue damage in a variety of diseases. Allergies and asthma as well as hyper-reactivity following infection are all immune system-mediated. Inflammatory responses against self antigens result in autoimmunity. Therefore, clinically it is important to be able to control inflammation. Some of the most effective techniques to control inflammation are aimed directly at T cells, especially at the various steps involved in T-cell activation and/or differentiation (Fig. 17.5).

One of the most attractive methods used to control inflammatory responses is to prevent T-cell activation. T-cell activation requires at least two signals. Signal one is antigen-specific and signal two is co-stimulatory. In the absence of signal two, T cells are rendered unresponsive (or anergic) to further stimulation. Blocking co-stimulation is an important method of controlling T-cell participation in inflammatory responses. In experimental systems, administration of antagonists of the B7/CD28 pathway have been shown to be effective at blocking the onset of T-cell responses to specific antigens, and at controlling ongoing autoimmune responses.²⁹ Targeting other pathways such as the CD40/CD154 co-stimulatory interaction that is involved in APC/T activation/differentiation has also been used experimentally to control ongoing Th1-mediated autoimmune diseases.³⁰ The CD40/CD154 pathway is required for B-cell differentiation, dendritic cell function, and production of effector cytokines, and plays an important role in Th1 differentiation via IL-12.

Regulation of inflammation by inhibiting recruitment of T cells and other effector cells is another method employed to control destructive immunopathologic responses. Because various selectins and integrins are required for efficiently targeting leukocytes to inflammatory sites, therapies directed at blocking the binding of these molecules to their ligands and at their blocking downstream signaling pathways are currently being employed to regulate inflammation. For example, the migration of T cells into the central nervous system in EAE, a Th1-mediated central nervous system-mediated autoimmune disease, can be blocked using antibodies to either the VLA-4 integrin or to CD44, which are required for T cells to cross the blood-brain barrier.³¹ Knowledge of chemokine secretion profiles during various inflammatory processes has resulted in the ability to control migration to inflammatory sites more specifically. Two methods of controlling chemokine-mediated trafficking are being evaluated: interruption of the chemokine gradient by systemic injection of purified chemokines and blocking chemokine/chemokine receptor interactions by the injection of specific antibodies. For example, accumulation of Th1 cells in the central nervous system in the SJL mouse EAE model can be inhibited by using antibodies specific for the MIP-1 α , a chemokine essential for migration of Th1 cells into the central nervous

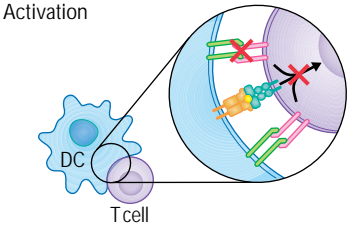

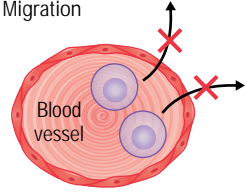

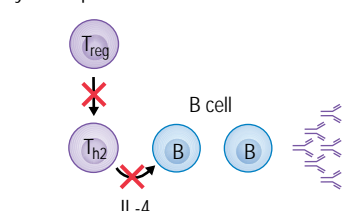

Process	Targets	Effects
 <p>Activation</p>	Costimulatory molecules Intracellular signaling molecules	Block T cell and APC activation Block proliferation Limit cytokine production Limit differentiation
 <p>Migration</p>	Chemokines Integrins	Prevent recruitment of T cells and effector cells into tissues Prevent effector function Prevent extravasation
 <p>Cytokine production</p>	Inflammatory cytokines Regulatory cytokines	Dampen effector cell activation and function Enhance effector function Prevent recruitment of T cells and effector cells into tissues

Fig. 17.5 Therapeutic regulation of inflammation. Several techniques have been employed to reduce T-cell responses in cases of inflammation. Among these are inhibiting T-cell activation and differentiation by blocking interactions with antigen-presenting cell (APC)-expressed co-stimulatory molecules (top) inhibiting naïve and effector T-cell trafficking by blocking molecules required for chemotaxis (middle), and limiting the effect of T-helper responses by decreasing the availability of inflammatory cytokines (bottom).

system parenchyma.⁷ Controlling T-cell trafficking by modulating chemokines is somewhat problematic because one must know the temporal expression pattern of the chemokines and chemokine receptors that are involved in the inflammatory process and compensate for the redundancy in chemokine/chemokine receptor binding.

Lastly, inflammatory processes can be regulated by neutralizing the pro-inflammatory cytokines (e.g., IFN- γ or TNF- α) and other effector molecules (e.g., iNOS, reactive oxygen intermediates, etc.) involved in the effector limb of the destructive processes. For example, neutralization of TNF- α using soluble TNF-receptor has proven to be an effective means of controlling inflammatory responses in an experimental autoimmune inflammatory model of multiple sclerosis³² and is an accepted clinical treatment for rheumatoid arthritis.

Cytotoxic lymphocyte function and natural killer cells

Stephen L Nutt, Sebastian Carotta, Axel Kallies

18

■ GENERAL INTRODUCTION TO CTL AND NK CELLS ■

Cytotoxic T lymphocytes (CTL) and natural killer (NK) cells represent two distinct but related lineages that are important for the control of viral, bacterial, and parasitic infections. These cells also play a prominent and complementary role in the sensing and elimination of malignant cells. Although the approaches by which CTL and NK cells kill their target cells and produce immunomodulatory cytokines are quite similar, the mechanisms by which they recognize their targets are distinctly different. CTL are CD8 T cells (Chapter 9) that recognize targets via the interaction of a diverse repertoire of polyclonally rearranged T-cell receptors (TCR) (Chapter 4) with a peptide-MHC class I complex (Chapter 6) and are a component of the adaptive immune response. MHC class I molecules are expressed on virtually all cells in the body and allow the CTL to scan the tissues for cells expressing foreign or cancer-associated peptides (Chapter 5). In contrast, NK cells are members of the innate immune system (Chapter 3) that use an array of invariant activating and inhibitory receptors to control their activity and specificity.¹ These fundamentally distinct approaches to the recognition of antigen allow for complementary functions, with CTL being specialized in detecting cells infected with intracellular pathogens such as viruses, whereas a prominent function of NK cells is to eliminate those cells where the pathogen or oncogene has blocked display of MHC class I molecules on the surface of the affected cell. As one of the principal immune-evasion mechanisms of viruses and tumors is to suppress MHC class I expression, NK cells provide a key line of defense against this strategy.

The importance of the lytic function of CTL and NK cells has been demonstrated in animal models as well as in patients with defective cytotoxicity. A number of recessive genetic syndromes that affect cytotoxic function have been reported, including familial hemophagocytic lymphohistiocytosis (FHL) that results from mutations in the perforin gene.² FHL patients present with severe immunodeficiency often associated with uncontrolled viral infections, including cytomegalovirus (CMV), herpes simplex virus (HSV) and Epstein-Barr virus (EBV). Similarly, mice genetically deficient or depleted for CTL and NK cells

■ CLINICAL RELEVANCE

FUNCTIONS OF CTL AND/OR NK CELLS

Protective functions include

- >> Host defense against:
 - most viruses, including HIV, EBV, and CMV
 - bacteria, including *Listeria monocytogenes*
 - parasites, including *Plasmodium falciparum* and *Toxoplasma gondii*
 - primary and metastatic tumors
- >> Positive regulation of:
 - graft versus leukemia effect
 - placental vascularization by uterine NK cells

Uncontrolled cytotoxicity contributes to

- some autoimmune disease, including diabetes and rheumatoid arthritis
- hypersensitivity reactions
- graft-versus-host disease
- transplant rejection

are overtly susceptible to viral pathogens as well as displaying impaired tumor rejection capabilities.²

With this potent ability to control pathogen-infected and malignant cells, it is not surprising that the modulation of cytolytic activity is an aim of many immune therapies (see Section 10). These strategies involve either the dampening of CTL function in situations such as transplantation or autoimmunity, or enhancing CTL and NK cell function via vaccination or cytokine therapy. However, tight controls need to be maintained over these effector cells, as deregulated CTL activity plays a direct role in a variety of immunopathological settings, including autoimmune diseases, hypersensitivity reactions, graft-versus-host disease and transplant

KEY CONCEPTS

CTL AND NK CELL EFFECTOR FUNCTIONS

- >> Cytotoxicity
 - killing by the perforin/granzyme pathway
 - death receptor mediated apoptosis, including Fas and TRAIL
- >> Immune modulation
 - inflammatory cytokine production, including IFN- γ and TNF
 - chemokine secretion, including CCL3 (MIP1 α), CCL4 (MIP1 β) and CCL5 (RANTES)
 - immunomodulatory cytokines, including IL-10 and GM-CSF

rejection. To maintain the right balance between killing unwanted or infected cells and not healthy neighboring cells, numerous layers of regulation operate to control cytotoxic functions.

EFFECTOR FUNCTIONS/MECHANISMS

CYTOTOXICITY

Cytotoxic cells kill their targets via two major pathways, perforin/granzyme-mediated lysis and death receptor-induced apoptosis. Both require intimate contact between the lytic cell and its target³ (Fig. 18.1). Although the processes are similar for CTL and NK cells, CTL lytic activity is acquired only after activation and differentiation, whereas NK cells have a 'natural killing' capacity that does not require pre-stimulation. In spite of this, NK cell killing is significantly increased by prior activation by cytokines or inflammatory signals. Both cell types also produce cytokines, most notably IFN- γ , that further enhance the immune response.

PERFORIN/GRANZYME PATHWAY

Perforin is a membrane-disrupting protein that, together with a family of serine proteases (granzymes), forms the bulk of lytic granules. The process of lysis has been most extensively studied in CTL, where, upon interaction between the TCR and an appropriate MHC class I peptide, a synaptic complex forms between the CTL and its target.³ Lytic granules can then be observed moving along a microtubule network toward the microtubule-organizing center that localizes at the synapse (Fig. 18.1). This process allows the polarized secretion of lytic granules precisely at the CTL–target cell interface. Perforin functions to disrupt the target cell membrane, including either the plasma membrane or the lysosomal membrane. Once the lytic lysosome is internalized into the target cell, it is granzymes that are the initiators of cell death. Granzymes function directly by cleaving substrates, or indirectly via a protease cascade, some of which are shared with pro-apoptotic caspases. One important substrate of granzyme B is the pro-apoptotic protein BID (*BH3-interacting domain death agonist*), which induces cell death via mitochondrial mediators such as

cytochrome c. Granzyme A, in contrast, kills via cleavage of nuclear proteins and facilitates double-stranded DNA breaks. Other granzymes must also play an important role in cytotoxicity, as mice deficient for both granzyme A and B are capable of tumor rejection and target cell lysis.²

DEATH RECEPTOR-INDUCED APOPTOSIS

Cytotoxic cells also have a receptor-based system to induce apoptosis of targets cells (Chapter 14). This pathway uses members of the tumor necrosis factor receptor (TNFR) superfamily that are expressed on the target cells. These receptors have an intracellular signaling motif, called the death domain, which recruits molecules such as FADD (*Fas-associated death domain*) that transduce the death signal. The two most prominent apoptosis-inducing TNFR family members are Fas (CD95)⁴ and TRAIL (*TNF-related apoptosis inducing ligand*).⁵ Whereas Fas is expressed on a wide variety of tissues, Fas ligand (FasL) expression is restricted to activated CTL and NK cells, where it is stored in lytic granules and, upon activation, released to the effector cell membrane. The Fas/FasL pathway is important in controlling T-cell numbers through activation-induced cell death (AICD), as well as in the rejection of some tumors (Chapter 14). Cytotoxic cells also express TRAIL, which upon binding to TRAIL receptors induces apoptosis in a wider selection of targets.⁵ Of particular therapeutic interest is the fact that tumor cells are often exquisitely sensitive to TRAIL.

CYTOKINES

Antigen-stimulated CTL and activated NK cells modulate the immune response by their ability to produce a variety of cytokines, most notably IFN- γ and TNF.¹ These potent inflammatory cytokines activate macrophages and lymphocytes at the site of infection. IFN- γ helps establish a Th1 response and further stimulates differentiated CTL. CTL and NK cells are capable of secreting a number of chemokines (Chapter 11), including CCL3, CCL4 and CCL5. These chemokines help recruit additional lymphocytes into the immune reaction.¹ NK cells are also a potent source of a diverse range of cytokines, including GM-CSF, IL-5, IL-10 and IL-13 (Chapter 10). The capacity to secrete a broad spectrum of cytokines provides NK cells with a wide range of regulatory capabilities.

CYTOTOXIC T CELLS

THE DEVELOPMENT AND TISSUE DISTRIBUTION OF CTL

CD8 T lymphocytes develop in the thymus, where they are selected for their ability to recognize nonself-peptides in the context of MHC class I molecules (Chapter 9). Upon thymic export these cells acquire a quiescent state and are termed 'naïve.' Naïve CD8 T cells circulate between the peripheral lymphoid organs such as the spleen and lymph nodes via the arterial and lymphatic systems. It is this circulation that allows the T cells to come in contact with antigen that has been brought to the lymphoid organs by dendritic cells (DC), and to initiate an immune response. The tissue distribution of lymphocytes is determined by

Fig. 18.1 Mechanisms of CTL-induced cell death. The CTL recognizes its target via the interaction of the TCR and the peptide-MHC class I complex on the target cell. TCR signaling induces the formation of an immunological synapse that is stabilized by the binding of LFA1 to ICAM-1 on the target cell. Lytic granules containing perforin, granzymes and FasL are polarized along microtubules and move toward the microtubule organizing center (MTOC). Lytic granules are then either endocytosed intact into the target cell, or their contents are secreted into the synapse by a process that requires perforin. Both mechanisms permit granzymes to gain entry into the target cell and induce apoptosis by caspase-dependent and independent pathways that result in DNA cleavage and mitochondrial damage. Membrane bound FasL can bind to its receptor on target cells and induce apoptosis independently of the perforin/granzyme pathway.

targeting proteins, which can be divided into three categories: selectins, chemokine receptors, and integrins.^{6,7} Naïve and activated CD8 T cells display distinct sets of these targeting proteins, allowing for the differential homing abilities of these cells (Chapter 12). Naïve CD8 T cells express high levels of the lymph node homing receptor L-selectin (CD62L) and CCR7, a receptor which recognizes the chemokines CCL19 and CCL21 that are produced in the T-cell areas of secondary lymphoid organs⁶ (Chapter 11). Here naïve T cells interact with antigen-presenting cells (APC), in particular DC (Chapter 7). If a naïve CD8 T cell does not encounter its specific peptide-MHC class I complex on the APC, it leaves the lymph node. This 'egress' is regulated by the sphingosine-1-phosphate receptor-1 (S1P₁).⁶ If, however, a CD8 T cell encounters the correctly presented peptide-MHC-I complex, a dramatic change in its localization and homing properties ensues. These CD8 T cells upregulate the high-affinity $\alpha_1\beta_2$ -integrin (LFA1) that mediates tight interaction between the CD8 T cell and the DC, shut down their egress program, and undergo multiple rounds of proliferation to become activated CTL. After the proliferative phase, the CTL then reacquire egress capacity by downregulating the molecules that recruited them to the lymph node in the first place, CD62L and CCR7.⁶ Egress also requires the re-expression of S1P₁ and the downregulation CD69, an early activation marker of T cells.

Activated CTL travel via the circulation to nonlymphoid sites where they tether to endothelial cells and extravasate into tissue. This

transmigration occurs in both inflamed and noninflamed sites, such as the skin, gut or lung. Many of the effector memory CTL are retained in nonlymphoid tissues, where they are poised to respond rapidly should the antigen be encountered again. A smaller number of memory cells reacquire CD62L and CCR7 expression and circulate through the blood and lymphoid organs and provide long-term memory.

THE CTL RESPONSE

The CTL response to an acute infection consists of three phases. First, the initial activation and proliferation of the CTL; second, the contraction of effector populations into memory cells; and third, the long-term maintenance of memory cells.

INITIAL ACTIVATION OF THE CTL RESPONSE

Naïve T cells constantly circulate through the secondary lymphoid organs, where antigen encounter occurs. For a CTL response, antigen is brought to the lymph node via the lymphatic system by APC (Fig. 18.2). These APC are typically DC that mature after antigen acquisition in the nonlymphoid tissues and migrate to the lymph node (Chapter 7). Although DC appear to be the most important 'professional' APC, macrophages and B cells are also able to present antigens in a similar manner. In the lymph node, naïve CD8 T lymphocytes scan the APC for the

presence of antigenic peptides presented on the MHC class I molecules, a process termed 'immune surveillance.' The scanning process is not completely random. In the case of an infection, inflammatory signals in the lymph node induce the chemokine receptor CCR5 expression on naïve CD8 T cells, which allows individual cells to be attracted to sites of antigen-specific DC-CD4⁺ T-cell interactions as signaled by a gradient of the chemokines CCL3 and CCL4.⁸ In the absence of a specific recognition by the TCR, the encounter is only transient and the T cell continues on to another APC to repeat the process. If the MHC class I-peptide complex is bound by the TCR and initiates signaling, a more lasting interaction occurs.

TCR activation promotes the polarization of the T cell and the formation of the 'immunological synapse.'⁹ (Fig. 18.1) The immunological synapse is a highly structured body that functions to concentrate TCR signaling in a defined area. It is associated with the selective recruitment of signaling molecules and exclusion of negative regulators. The synapse is stabilized by a ring of adhesion molecules, including, for example, LFA1, which binds to ICAM1 on the target cell (Fig. 18.1). For a T cell to become fully active, co-stimulation through a second signaling pathway is required. Many co-stimulators have been identified that share the common characteristic of being transmembrane receptors, often of the TNFR superfamily, that bind transmembrane ligands on the APC. The most important co-stimulator, CD28, binds the ligands CD80 (B7.1) and CD86 (B7.2), both of which are expressed on activated APC. Co-stimulation results in the clonal expansion of CTL with the selected antigen specificity. The expression of CD80/86 is tightly regulated.

High-level expression occurs only after an APC receives activation signals, such as inflammatory cytokines, or components of the pathogens itself, such as lipopolysaccharide. Co-stimulation via CD28 is most critical during the initiation of the immune response, as it promotes IL-2 production which, in turn, supports the development of memory T cells.¹⁰ Naïve T cells that receive TCR stimulation in the absence of co-stimulatory signals can become nonresponsive to antigen, a state termed 'anergy.'

Cross-presentation and priming

After it was established that only direct interaction with an APC and appropriate co-stimulation led to full CTL activity, a problem arose in explaining the mechanism by which antigens in non-APC were recognized by CTL. This dilemma was resolved by the discovery that there are two distinct mechanisms by which CTL encounter peptide-MHC class I complexes.¹¹ If the APC expresses the antigen, for example if it is infected by a virus, then the APC can process the antigen via the endogenous MHC class I pathway for presentation. The more intriguing situation arises when the APC does not express the antigen. In this case the APC – most notably DC, but also macrophages and B cells – are thought to acquire and process the antigen via a process termed 'cross-presentation'¹¹ (Chapter 7). Cross-presentation is initiated by the capture of foreign or exogenous antigens by phagosomes. The antigens are then processed by an unusual mechanism that directs the peptides to the MHC class I pathway and presentation on the cell surface. An encounter of a CTL with an antigen processed in this

Fig. 18.2 Immune cell interactions during an immune response in the lymph node. After their encounter with antigen DC move to the draining lymph node, where they initiate an antigen-specific immune response. In the very early stages, NK cells are recruited to the lymph node and modulate various aspects of this response. NK cells provide cytokines that induce the maturation of DC, which enables these cells to efficiently present the antigen to T cells in the context of co-stimulatory signals. NK cells also have the ability to eliminate immature DC and to provide 'early' IFN-γ for the initiation of a Th1-type CD4 T-cell response. Finally, NK cells produce a range of chemokines, most notably CCL3 (MIP-1α) and CCL4 (MIP-1β), which are crucial for the recruitment of CD8 T cells into the immune response.

pathway is termed 'cross-priming'.¹¹ This strategy assists the CTL in viral control in two ways. First, cross-priming alleviates the need for the DC to be infected for detection, and therefore prevents viruses escaping immune detection by avoiding infecting DC. Second, viruses often attempt to evade CTL by downregulating the MHC class I pathway. Cross-priming occurs in noninfected cells that are still fully capable of MHC class I presentation, and thus remain able to stimulate CTL activity.

THE CONTRACTION OF EFFECTOR POPULATIONS INTO MEMORY CELLS

After activation of the CTL in the secondary lymphoid organs, an immune response is characterized by the rapid proliferation of antigen-specific cells and their acquisition of effector functions. CTL proliferate at one of the fastest rates known for mammalian cells, with a cell cycle time of approximately 6 hours in both humans and rodents. Infection leads to a dramatic increase in the numbers of pathogen-specific CTL, from almost undetectable initial levels to several million cells in the course of a single week. The magnitude of this response is dependent on the kind of infection and the dose of the antigen. It is controlled by the number of precursors recruited into the response.¹² The expansion phase is followed by a contraction of the CTL population that is independent of both the magnitude of the response and clearance of the antigen. This phase is essential to prevent nonspecific tissue damage through uncontrolled cytokine release and cytolytic activity. Contraction also preserves the flexibility of the T-cell response to new infections while memory of previously encountered antigens is maintained. Typically 5% of the expanded effector cell population survives in the long-lived memory pool.¹³

THE LONG-TERM MAINTENANCE OF MEMORY CELLS

The production of long-lasting antigen-independent memory cells is essential for a rapid response should re-infection occur. CTL memory provides a more vigorous response than the primary challenge for both quantitative and qualitative reasons.¹⁴ Quantitatively, owing to the substantial clonal expansion during a primary infection, the precursor frequency of antigen-specific CTL is vastly higher in immune

individuals than in naïve subjects, thus allowing for a stronger response. Qualitatively, memory CTL exhibit a striking efficiency in elaborating effector functions associated with the rapid production of IFN- γ . This enhanced response is the result of reprogramming of gene expression profiles by epigenetic changes in DNA methylation or chromatin structure. The CTL memory compartment is composed of two cell types, effector memory (T_{em}) and central memory (T_{cm}). These subsets differ in their surface molecule expression and in their ability to exhibit effector functions¹² (Table 18.1). Like their naïve counterparts, T_{cm} express high levels of CD62L and CCR7 and reside primarily in the secondary lymphoid organs. T_{cm} are capable of prolonged homeostatic self-renewal in the absence of antigen. However, upon antigen encounter they rapidly gain effector function and acquire a T_{em} phenotype. T_{em} are characterized by low expression of CD62L and CCR7 and are distributed throughout the body, including peripheral tissues such as lung and gut, where they can immediately confront invading pathogens. Both T_{em} and T_{cm} express high levels of CD44, which distinguishes them from naïve T cells (Table 18.1). The pathway(s) of development of these distinct memory cell types is not fully understood. The conventional linear model of memory formation proposes that memory cells are derived directly from the remaining effector cells after the contraction phase.¹² An alternative model proposes that pathways exist that allow the differentiation of memory cells without passing through an effector stage. CD4 T cell help and cytokines, including IL-15 and IL-7 and their receptors, have been identified as crucial for the survival and maintenance of the memory T-cell pool.¹³

CD4 T-CELL HELP

The final player in the initial activation of CTL is the 'help' provided by CD4 T cells specific for an antigen linked to the CTL epitope¹⁰ (Chapter 17). The discovery of cross-priming by DC led to a model whereby both CD4 and CD8 T cells recognize antigen on the same APC via MHC classes II and I, respectively.¹¹ Subsequent studies demonstrated that the function of the CD4 T cells in the process is to activate the DC. The requirement for CD4 help to generate a CTL response in the absence of an inflammatory stimulus contrasts with the fact that CD4 T cells are not required for a strong primary CTL response to many model

Table 18.1 Properties of CTL populations

Marker	Naïve CTL	Effector memory (T_{EM})	Central memory (T_{CM})
CD62L	++	–	++
CD44	+	+++	+++
CCR7	+	–	+
IL7R (CD127)	+	–	+
IL2R β (CD122)	+	++	+++
Main tissue distribution	Lymph nodes, spleen, blood	Nonlymphoid tissue (lung, liver), spleen	Lymph nodes, spleen, blood
Cytotoxic function	–	++	–
IFN- γ	–	+++	+

infectious agents, such as lymphocytic choriomeningitis virus (LCMV) and *Listeria monocytogenes*.¹⁰ This CD4 independence is explained by direct activation of the APC by the pathogen through activation of the Toll-like receptors that induce pro-inflammatory cytokines, thereby bypassing the need for CD4 help. It is likely that a role for help in primary responses depends on a number of variables, such as the degree of APC activation, inflammatory cytokine production, mode of infection or immunization, and the sensitivity of the assays employed to detect primary and memory CTL responses.

The processes by which help is provided are poorly understood. It is likely that cytokines such as IL-2 are involved. These cytokines promote the survival, proliferation and programming of the memory CTL.¹³ They are provided either directly by the CD4 T cells or by an intermediate cell stimulated by CD4 T cells. CD4 T cell-deficient mice have been developed to study these CTL responses. Interestingly, 'helpless' CD8 T cells strongly resemble CTL in chronic infections in which pathogens are not cleared despite a robust CTL response. In these studies two molecules have been found that mediate the defects in helpless CTL responses. Firstly, re-stimulation of helpless CTL leads to an abortive response due to AICD that is mediated by TRAIL.¹⁵ Secondly, PD-1 (programmed death 1), an inhibitory member of the TNFR family, is expressed on both helpless CTL and on CTL cells during chronic infections. Blocking the interaction of PD-1 with its ligands greatly enhances the numbers and functions of the impaired CTL.¹⁶

DETECTION AND ANALYSIS OF CTL FUNCTION

Much progress in our understanding of the generation of CTL in an immune response has resulted from the development of several accurate and sensitive assays for CTL function. Traditional CTL assays were performed on bulk populations of effector cells and included chromium (⁵¹Cr) release assays. In these assays, target cells are labeled with ⁵¹Cr and then pulsed with peptide-antigen. Peptide-specific CTL are incubated with the target cells. Lytic activity is then measured by the release of ⁵¹Cr into the culture supernatant. Although the release of ⁵¹Cr represents a powerful quantitative assay for CTL activity, it has the distinct disadvantage of requiring pre-stimulation of the CTL population for 1–2 weeks to expand the numbers of antigen-specific CTL to detectable levels. This limitation made it difficult to study the phenotype of specific cells *in vivo*. In mice this limitation was overcome by the development of animals that were monoclonal for the TCR. These mouse strains express transgenic TCR that recognize either MHC class I (CD8) or MHC class II (CD4) specific epitopes. Such T cells, which are specific for a single peptide, have proved extremely useful in the study of CTL responses, as antigen-specific cells can be easily detected.

Although they are powerful tools, TCR transgenic mouse models have some limitations, as they do not fully recapitulate the diversity of the normal immune response and represent an approach that cannot be used in human studies. The development of labeled tetramers of MHC class I–peptide complexes that bind to the endogenous TCR has made a major contribution to alleviating these previous limitations, as they allow the detection of antigen-specific CTL within a polyclonal population.¹⁷ This

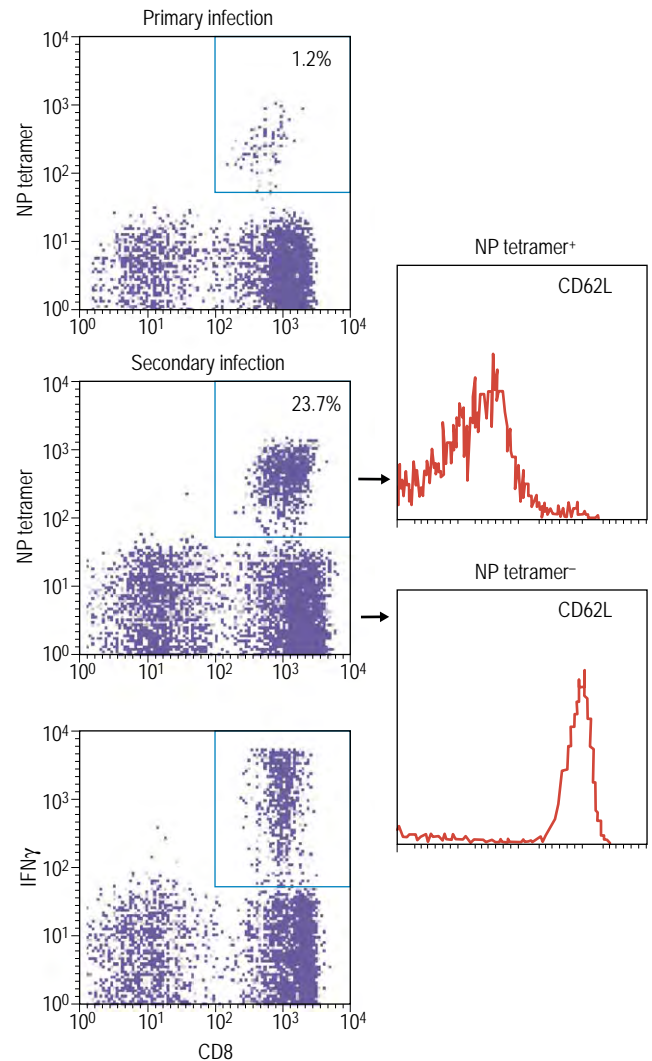

Fig. 18.3 Monitoring a virus-specific CTL response. A fluorescent-labeled tetramer complex comprising an MHC class I molecule and a virus-specific peptide (NP) is used to detect NP-specific CD8 T cells in the spleens of mice infected with influenza virus. During the primary response, virus-specific CTLs expand in the draining lymph node of the lung and later exit to the lung and spleen (upper left). After the infection is resolved, a small population of virus-specific memory CTLs resides in the spleen. A second infection with influenza results in very high numbers of virus-specific CTLs in the spleen (middle left) and lung. Specific CTLs can be re-stimulated with the NP peptide *in vitro*, inducing IFN- γ secretion that is detected by intracellular staining with a labeled anti-IFN- γ antibody (lower left). Staining with an antibody to CD62L shows the typical profile of effector memory T cells (T_{EM}) in the NP-tetramer positive CTL (upper right) and of naive CD8 T cells in the tetramer negative population (lower right).

technique is simple and broadly applicable. It can accurately detect rare antigen-specific populations from patient material or animal tissue (Fig. 18.3). The ability to prospectively identify antigen-specific CTL has been combined with single-cell functional assays such as ELISpot or intracellular cytokine assays. These techniques enable the identification of individual cytokine or chemokine-secreting CTL in a population by either flow-cytometric or colormetric (ELISpot) assays (Fig. 18.3). The finding that the lysosomal compartment proteins LAMP1/2 (CD107a/b) can be detected on the cell surface of degranulating CTL provides an equally powerful flow cytometry-based single-cell assay to investigate CTL lytic function.¹⁸

■ NATURAL KILLER CELLS ■

PROPERTIES OF NK CELLS

NK cells are a lymphoid lineage that, owing to the absence of antigen-receptor rearrangements, belong to the innate immune response. Compared to CTL, NK cells are relatively large, granular, and do not require pre-activation in order to recognize and lyse malignant or aberrant cells. NK cells also produce copious amounts of cytokines and chemokines, which enable them to modulate the immune response. Whereas the development of B and T lymphocytes has been extensively studied and anatomical sites and major mediators are well characterized, NK cells have proved more elusive. Part of the problem lies in their relative scarcity, amounting to less than 2% of cells in bone marrow or spleen and to ~15% of the lymphocytes in blood. The lack of appropriate markers to distinguish NK cells, coupled with phenotypic heterogeneity between species and within mouse strains, has also complicated their analysis. In recent years it has become apparent that NK cells develop in the bone marrow from a lymphoid progenitor, although a bipotent thymic NK/T progenitor also occurs in fetal and to a lesser extent in adult life.¹ The potential of bone marrow progenitors to make NK cells can be assayed *in vitro* through cell culture in the presence of a cocktail of cytokines that most importantly includes IL-15. IL-15 is essential throughout NK-cell development *in vivo*, but can be substituted for *in vitro* by high concentrations of IL-2. The IL-15R consists of three components, the IL-2/15 β chain (CD122), a unique IL-15R α chain, and the common γ chain, which contains the intracellular signaling component of the receptor.¹⁹ The importance of this receptor complex is emphasized by the lack of NK cells in X-linked SCID patients, and in dogs and mice that have mutations in the common γ -chain gene. In contrast to the B- and T-cell lineages, where the requirement for cytokines changes throughout their development and activation state, NK cells appear to constantly require IL-15 for their survival.¹ However, the IL-15/IL-15R complex does not function in a manner similar to other cytokines that are produced as soluble ligands and bind to their receptor in a paracrine or autocrine manner. Surprisingly, IL-15 is virtually undetectable in body fluids or cell culture supernatants, despite the ubiquitous distribution of the mRNA. The solution to these paradoxical observation is that IL-15 function requires the presence of the IL-15R α in the same cell. The IL-15/IL-15R α complex is then presented on the cell surface *in trans* to the NK cell expressing the IL-15R $\alpha\beta\gamma$ complex.¹⁹ In this manner IL-15 is thought to maintain the homeostatic levels of NK cells in the body. Once NK cells have acquired IL-15 responsiveness, they proceed through an ordered differentiation process that

results in an expansion phase and the acquisition of a panel of activating and inhibitory receptors.^{1,20} It was previously assumed that these NK cells were fully functional, but recent data suggest that NK cell maturation entails multiple steps and activation states.^{21,22}

TISSUE DISTRIBUTION AND DIVERSITY OF NK CELLS

In line with their surveillance function, NK cells are found at many sites in the body. In mice, where the tissue distribution has been thoroughly studied, NK cells are found in bone marrow, peripheral blood, and spleen. NK cells also represent one of the predominant hematopoietic cell types in diverse organs such as liver, lung, and the decidual lining of the uterus. Few are present in nonimmunologically activated lymph nodes or thymus.

The broad range of tissue distribution suggests that there is diversity in the function of mature NK cells. Indeed, human NK cells can be divided into two subsets based on the expression of CD16 (Fc γ RIII) and the adhesion molecule CD56 (Fig. 18.4). CD56^{dim} NK cells represent >90% of the peripheral blood NK cells, are CD16⁺KIR⁺, and display greater cytotoxicity. By contrast, CD56^{bright} NK cells show greater proliferative potential, greater cytokine production, and are the principal NK cell population in secondary lymphoid organs.²³ Recently it has been shown that NK cell progenitors that are CD56^{dim} develop through a series of intermediaries into CD56^{bright} cells.²¹ It is not clear whether the CD56^{dim} cells in the blood represent an even more mature cell stage or a separate sublineage.

One important limitation in understanding the functional role played by the NK-cell subsets has been the inability to identify populations corresponding to the CD56^{bright} and CD56^{dim} populations in rodents, as this antigen is not expressed in mouse NK cells.²³ Recently NK cell heterogeneity, based on the differential expression of CD11b (integrin α_M) and CD27, has been dissected in the mouse. Whereas developing NK cells in the bone marrow are CD27⁺CD11b^{dim}, these cells differentiate into CD27⁺CD11b^{bright} and CD27⁻CD11b^{bright} stages in the spleen. Interestingly, it is the CD27⁺ cells that are found in lymph nodes, whereas the CD27⁻ NK cells are localized predominantly to the peripheral blood and lung.²² In a pattern similar to that of CD56 expression in human NK cells, the level of CD27 in mouse NK cells was shown to correlate with the proliferative potential of the NK-cell subset. Whether these CD27 populations represent the equivalent of CD56 human NK-cell subsets remains to be determined.²²

■ CYTOKINE REGULATION OF NK-CELL ACTIVATION, FUNCTION AND HOMEOSTASIS ■

NK cells rely on IL-15 for their development and homeostatic maintenance in the peripheral organs. However, cultured NK cells also respond to other cytokines, including IL-2, -4, -12, -18 and -21.^{1,24} Surprisingly, NK cell numbers are relatively normal in mice deficient for these other cytokines, suggesting that they may be more important for function than for development.²⁵ The IL-2R shares its β and γ subunits with the constitutively expressed IL-15R. The dimeric IL-2R $\beta\gamma$ is able to respond to the high levels of IL-2 supplied *in vitro* to induce proliferation and the

Fig. 18.4 Schematic representation of human NK cells. The human NK cell subsets show distinct receptor expression and effector functions. CD56^{bright} NK cells produce high levels of cytokines and have patterns of chemokine and homing receptor expression that distinguish them from CD56^{dim} NK cells. CD56^{dim} NK cells express high levels of KIR and cytotoxic activity. The relative levels of receptors and effector molecules is indicated on an arbitrary scale, with +/- being weak and +++ being strong expression.

induction of NK cells that were historically called lymphokine-activated-killer or LAK cells. IL-2 activation will also induce the IL-2R α chain to complete the high-affinity trimeric receptor. IL-4 activates human NK cells, and promotes the proliferation of a fraction of NK cells characterized by their ability to produce IL-13.

The myeloid-derived factors IL-12 and IL-18 have profound effects on NK-cell function. IL-12 and IL-18 are produced by macrophages and DC during inflammatory immune activation, such as viral infection.²⁶ While NK cells are present in IL-12- or IL-18-deficient mice and only marginally reduced in double mutant animals, cytotoxic activity and the ability to respond to infections such as mouse CMV (MCMV) is impaired.²⁶ Cultivation of NK cells in IL-12 and/or IL-18 induces short-term activation, cytotoxicity and IFN- γ production, whereas longer cultures produce more specialized cytokine-producing cells.

A recently identified NK cell-activating cytokine is IL-21.²⁴ IL-21 is a member of the common γ chain family of cytokines produced by CD4 T cells and, in contrast to IL-2 or IL-15, does not promote proliferation. Instead, it enhances maturation and effector function. Mouse NK cells treated with IL-21 display a broad-spectrum increase in cytotoxic function and produce cytokines including IFN- γ and IL-10.²⁴ Importantly, mice treated with IL-21 show a marked increase in NK cell-mediated tumor rejection, highlighting the potential for use of this cytokine in anti-cancer therapeutics.²⁴ Human NK cells respond similarly to IL-21, but there is also a role for IL-21 in early NK development that is not present in the mouse.

NK CELL RECEPTORS

NK cells differ from CTL in that they do not require the expression of MHC class I to recognize target cells. In fact, the re-introduction of MHC class I molecules into previously susceptible cell lines confers resistance to NK cell-mediated killing. These observations led to the missing-self hypothesis, which proposes that NK cells survey tissues

KEY CONCEPTS

NK CELL RECEPTORS

- >> Inhibitory receptors:
 - recognize mostly MHC class I ligands with high affinity
 - signal via ITIM motifs
 - recruit phosphatases (SHP and SHIP) to prevent a cytotoxic response
 - required for NK cell licensing
- >> Activating receptors:
 - do not bind MHC class I molecules with high affinity
 - ligands include viral molecules and stress induced proteins
 - signal via ITAM motifs.
 - use several signaling adaptors, including DAP12

for the usually ubiquitous MHC class I expression.²⁷ Encounter with MHC class I sends an inhibitory signal to the NK cell, which then moves on in search of other targets. However, if a cell downregulates MHC class I to avoid CTL activity, these cells are killed by NK cells. The missing-self hypothesis, although altered over time to encompass other observations, has been extremely useful in providing a predictive framework by which to investigate NK-cell receptors and the recognition of target cells (Fig. 18.5).

In the past two decades a large number of NK cell receptors have been identified,²⁰ the ligands for many of which are known. Although a number are the MHC class I molecules themselves, as predicted by the missing-self hypothesis, there are many other types of ligand. NK-cell receptors are classified into either activating or inhibitory types. This distinction was initially based on the *in vitro* properties of antibodies against these receptors, but is increasingly regarded as the expression of

Fig. 18.5 NK cell recognition of target cells. NK cells express inhibitory receptors for MHC class I and activating receptors for a variety of cellular, viral and stress-induced ligands that alter the outcome of encounter with a target cell. The missing-self hypothesis initially predicted that NK cells would be activated to kill in the absence of MHC class I inhibition. However, an activating signal is also required. This activating signal can be provided by cellular ligands, or by viral or stress-induced proteins, termed 'altered self.' In the presence of both inhibitory and activating signals the outcome is determined by quantitative differences in signal strength between the two.

Table 18.2 Human and mouse NK cell receptors (partial list)

Gene	Function	Ligands
Human		
LILRB1	Inhibitory	HLA-A,B,C,E,F,G,CMV UL18

NKR-P1D	Inhibitory	Clr-b

the biochemical signal-transduction pathways activated by the receptor.²⁰ Interestingly, although this conceptual strategy of target recognition is conserved in all mammals tested, rodents and humans have evolved their receptors from two independent gene families. The killer immunoglobulin-like receptors (KIR) in humans and the Ly49 family in mice perform the same function (Table 18.2).

NK-CELL RECEPTOR SIGNALING

The signals derived from NK receptors are defined as inhibitory or activating in terms of their effect on NK-cell function. All extensively characterized inhibitory receptors carry an immunoreceptor tyrosine-based inhibitory motif (ITIM) in their intracellular domain. Ligation of ITIM-containing receptors causes tyrosine phosphorylation and the recruitment of a variety of phosphatases, including SHP and SHIP, that act to damp downstream signaling pathways and NK-cell effector functions.^{20, 28} In contrast, activating receptors use immunoreceptor tyrosine-based activation motifs (ITAM) to transduce stimulatory signals. Engagement of an ITAM-containing receptor results in tyrosine phosphorylation and recruitment of adaptor molecules, including FcεR1γ, CD3ζ, or DAP12. The best-characterized activating receptor is CD16, an Fc receptor that binds IgG and is responsible for the antibody-dependent cytotoxic capacity (ADCC) of NK cells. CD16 recruits FcεR1γ and CD3ζ, which in their turn attract the tyrosine kinases syk and ZAP70.²⁰ These pathways then promote effector functions via multiple signal transduction pathways.

NK CELL RECEPTORS THAT RECOGNIZE MHC-I MOLECULES

NK cells recognize a wide variety of MHC class I molecules of both classic and nonclassic types. The receptors providing this recognition fit broadly into the immunoglobulin-like and lectin-like superfamilies. They show significant differences between mice and humans.

KILLER CELL IMMUNOGLOBULIN-LIKE RECEPTORS (KIR) IN HUMANS

The *KIR* genes represent a family of 15 genes that are physically linked on chromosome 19.²⁹ The locus shows a high degree of variation in the human population, with both the number of *KIR* genes varying between individuals and extensive allelic polymorphisms described. The *KIR* family was originally called killer inhibitory receptors, but subsequent studies have demonstrated that activating receptors are also encoded by the *KIR* locus. As expected, the inhibitory KIR contain ITIM, whereas all activating KIR utilize DAP12 to transduce signals from an ITAM.^{20, 30} Individual *KIR* genes are expressed by only a

subset of NK cells. This expression pattern is stably maintained in a clonal manner. Similarly to most other NK-cell receptors, KIR can also be expressed by some T cells after activation.

KIR recognize the human MHC class I molecules HLA-A, B and C (Table 18.2). The specificity of the inhibitory KIR has been extensively characterized, with, for example, the different isoforms of KIR2D recognizing all known alleles of HLA-C.²⁰ The ligands of the activating KIR are less clear; however, they do not bind with high affinity to HLA molecules. KIR2DL4 is the most evolutionarily distinct member of the family and appears to be expressed in all activated NK cells in culture and on the CD56^{bright} subset in peripheral blood. KIR2DL4 also has some distinct structural features and may act as an unconventional activating receptor binding HLA-G.²⁹

There are emerging epidemiological data implicating particular KIR in a variety of autoimmune pathologies and viral responses.²⁹ For example, individuals with KIR2DS2 and some HLA-C alleles are predisposed to rheumatoid arthritis with vascular complications. Conversely, HIV-infected individuals who are homozygous for HLA-Bw4 progress to AIDS more slowly than those with other haplotypes, especially when they have the *KIR3DS1* gene. The mechanism by which this occurs is unknown, but the activity suggests that KIR recognize a HIV-associated peptide in the context of HLA-Bw4³¹ (Chapter 37).

THE LY49 FAMILY IN RODENTS

In a remarkable example of the power of selection to shape the evolution of the immune system, a multigenic locus with functional properties almost identical to those of the *KIR* genes has evolved independently in rodents. Mice, which have only two *Kir* genes of unknown function, have an analogous cluster of type II transmembrane spanning lectin-like genes called the *Ly49* family.²⁰ This family consists of more than 20 members and is highly polymorphic between mouse strains. Like KIR molecules, Ly49 receptors are also highly variegated in their expression in NK cells, and they are monoallelically transcribed. *Ly49* genes encode activating and inhibitory receptors that bind to MHC class I molecules and signal via ITAM and ITIM motifs, respectively (Table 18.2). Ligand-binding studies have revealed that the inhibitory Ly49 receptors such as A, C, and I bind to MHC class I haplotypes and function to prevent autoaggression by NK cells. The function of the activating receptors has proved more difficult to elucidate. Ly49D is known to have high affinity for the MHC class I H-2D^d allele and is involved in rejecting bone marrow allografts expressing H-2D^d, whereas the function of Ly49D in the normal immune response is unclear. For one activating receptor, Ly49H, the physiological function is known, as it recognizes the m157 molecule of MCMV and is important in viral control.³²

CD94 AND NKG2 FAMILY

Unlike the KIR or Ly49s, the CD94/NKG2 complex is present both in rodents and humans. CD94/NKG2 receptors recognize nonclassical MHC class I ligands, such as HLA-E in humans and Qa1^b in mice. A single *CD94* gene is physically linked to four *NKG2* (A, C, E and a truncated F) genes in humans. CD94 is found on the cell surface either alone or with the NKG2 proteins. The NKG2 family also exists in activating (C, E) and inhibitory types (A). Interestingly, both the activating and the inhibitory complexes recognize HLA-E that present predominantly the leader peptides of other HLA molecules, but not HLA-E itself. This system may provide a mechanism for the NK cells to monitor the expression of multiple MHC class I proteins using HLA-E as a surrogate.²⁰

NKG2D

NKG2D, which is only distantly related to the *NKG2* family, is a single, nonpolymorphic gene that is expressed on all NK cells from an early stage. In the mouse NKG2D signals through both DAP12 and another adaptor, DAP10, whereas human NK cells use only DAP10.²⁰ Activation of NKG2D using a specific antibody results in enhanced cytotoxicity and cytokine secretion.³³ The ligands of NKG2D are a family of molecules with structural similarity to MHC class I proteins, including MICA/B and ULP1-4 in humans and RAE-1, H60 and MULTI in mice. These ligands represent a diverse array of sequences, yet all bind with high affinity to NKG2D.³⁴ Interestingly, the MIC family in human is highly polymorphic, suggesting that in this receptor–ligand interaction the diversity comes from the ligands rather than the receptors. Transfection of otherwise resistant tumor cells with NKG2D ligands restores the susceptibility of these cells to NK-cell cytotoxic function. The key to understanding NKG2D function lies in the fact that the ligands are inducible and provide a mechanism for NK cells to detect stressed tissue, such as virally infected or malignant cells,³⁴ a phenomenon that has been termed ‘altered self’ (Fig. 18.5).

NK RECEPTORS THAT RECOGNIZE NON-MHC-I MOLECULES

Beyond the multiple systems of activating and inhibitory receptors they have evolved to recognize MHC class I molecules and their structural variants, NK cells also have several other receptor families that bind nonMHC class I ligands. These include the NKR-P1 family, which is a polymorphic multigene family in rodents consisting of activating (A, C, F) and inhibitory forms (D), but consists of only a single member in humans, whose activity is inhibitory. The ligands for some family members have been recently reported and are themselves lectin family receptors, including clr-b and clr-g in mice and LLT1 in humans. The biological significance of these interactions is still unresolved.²⁰ Another NK receptor that is conserved between species is CD244 (2B4), a pan-NK cell-expressed molecule whose ligand is CD48. Based on antibody cross-linking studies, human CD244 is designated an activating receptor. However, recent analysis of CD244-deficient mice suggests that the mouse homolog is inhibitory.²⁰ A number of additional activating receptors exist, including the natural cytotoxicity receptors NKp30,

NKp44 and NKp46. NKp30 and NKp46 are broadly expressed on human NK cells, and NKp46 is expressed on all mouse NK cells. NKp44 is specifically expressed on activated human NK cells. These receptors can be activated by antibody cross-linking and, although their ligands are unknown, there is evidence that heparan-sulfate proteoglycans are involved in target recognition. NKp46 binds hemagglutinin on influenza virus-infected cells, and mice deficient for NKp46 have impaired response to influenza infection.³⁵ Therefore, the natural cytotoxicity receptors are likely to play a critical role in some aspects of NK cell function.

NK CELL LICENSING AND SELF-TOLERANCE

The plethora of MHC class I-binding inhibitory receptors, as proposed by the missing-self hypothesis, explains the influence of MHC class I on NK-cell lytic function against tumors. However, how self-tolerance is achieved has been less clear. The initial theory to explain self-tolerance was the ‘at least one receptor’ model, which proposed that NK cells must express at least one self-MHC class I inhibitory receptor. A second model suggested that the receptor repertoire is shaped by selection by the specific MHC haplotype and the presence of self-ligands. The observation that NK cells are not autoreactive in the absence of any inhibitory ligands (MHC class I-deficient mice) and are actually poor killers suggests that the situation is more complex than these models would allow for.²⁷ A concept termed ‘licensing’ has been proposed to account for these observations.³⁶ Under this model, NK cells need to acquire functional competency through binding of at least one inhibitory receptor before they can be activated and display cytotoxic function. This model predicts that there are two types of tolerant NK cell: those that express an inhibitory receptor and are licensed, and those unlicensed NK cells that are functionally incompetent. Data to support this model come from the poor responsiveness of mouse NK cells that do not express any known inhibitory receptor. More definitive support comes from transgenic mice that express only a single MHC class I that is recognized by only a subset of NK cells expressing the inhibitory receptor Ly49C.³⁶ As predicted by the licensing model, only those NK cells expressing Ly49C are licensed and functionally competent to respond to stimulation. Whether unlicensed NK cells can still have a function is unclear, but inflammatory signals can, at least partially, overcome the defects in unlicensed cells, suggesting that they may play a role in some circumstances, such as viral infection. As these studies were performed in mouse models, another crucial question is whether human NK cells with their similar strategies of receptor expression and function also utilize a licensing process.

SPECIFIC NK-CELL FUNCTIONS

The increasing ability to separate NK cells from T cells both phenotypically and genetically has greatly enhanced the understanding of NK-cell functions. Although some cytotoxic and immunomodulatory capacities overlap with those of T cells, it is also apparent that some functions of NK cells are unique. Specific examples of NK-cell functions are discussed below.

CONTROL OF VIRAL INFECTIONS

NK cell activity rises early in the course of viral infection, partly driven by the release of IL-12, IL-18 and IFN- α/β , which stimulates activation²⁸ (Chapter 27). The evidence that NK cells are essential for host defense against viruses comes directly from patients and mice lacking NK-cell function and indirectly from viral strategies to avoid NK-cell recognition. Human patients with selective deficiencies in NK cells show a pronounced susceptibility to recurrent severe infections, especially with HSV and CMV.

A powerful example of the role NK cell-activating receptors in viral control is NK cell-mediated resistance to MCMV. Mouse strains that lack Ly49H are highly susceptible to MCMV, leading to uncontrolled viral replication and death.³² Importantly, this protection is mediated by the recognition of the m157 protein of MCMV by Ly49H. As a consequence, whereas in the early stages of MCMV infection the NK-cell response is nonspecific, subsequent control of the virus depends on the proliferation and effector function of the Ly49H⁺ NK-cell subset in the presence of the activating ligand. The rapid accumulation of Ly49H⁺ NK cells during MCMV infection is the first example of clonal expansion of NK cells in a manner similar to that of B and T cells.³²

There is also emerging evidence that NK cells have direct effects on the progression of HIV infection³¹ (Chapter 37). NK cells are able to lyse HIV-infected target cells either directly or by ADCC, but despite this ability, NK-cell responses are impaired in HIV-infected patients as infected T-cell blasts selectively downregulate some HLA genes to avoid CTL activity but remain resistant to NK-cell cytotoxicity. NK cells also secrete large quantities of the chemokines CCL3, CCL4 and CCL5, which are the ligands for CCR5 and inhibit CCR5-dependent entry of HIV into target cells. These findings are supported by studies that show that high-risk, but uninfected, individuals appear to have increased NK-cell activity, and that the combination of the expression of HLA-Bw4 and the KIR3DS1 gene is associated with delayed progression to AIDS.³¹ Finally, HIV viraemia induces several functional abnormalities on NK cells, suggesting that this complex virus and NK cells interact at multiple levels.

CONTROL OF MALIGNANT CELLS

A function for NK cells in protective tumor immune surveillance, although hypothesized many years ago, is still uncertain. One limitation in testing this hypothesis has been the lack of a mouse model that is NK-cell deficient but has an otherwise competent immune system.²⁸ There is good evidence that NK cells can reject tumor cells in animal models, and that the administration of several cytokines that enhance NK-cell function, including IL-2, IL-12 and IL-21, or those that induce IFN- α production, are protective against metastasis.³⁷ In light of this, there have been many clinical trials to assess either cytokine treatment or the injection of *ex vivo* treated NK cells (Chapter 94). Unfortunately, the high doses of IL-2 required for efficacy are relatively toxic, and transferred NK cells have proved difficult to target to tumors.²⁸ Despite this, some successes have been demonstrated for melanoma, lung and hepatic cancers. Current trials are now testing combination therapies such as low dose IL-2 and IL-12 or IFN- α .

ROLE OF NK CELLS IN HEMATOPOIETIC STEM CELL TRANSPLANTATION

NK cells in an F₁ offspring of two mouse strains can reject parental bone marrow, a process termed 'hybrid resistance.' This is in contrast to organ grafts from the same mice that are tolerated by CTL owing to their expression of MHC class I molecules from each parent. This phenomenon has recently been found to be mediated by the interaction of host NKG2D and its ligands, RAE-1, on the repopulating bone marrow cells, as treatment with a neutralizing antibody to NKG2D prevented hybrid resistance.³³ These studies raise the possibility that other stem cells or tissues upregulate the expression of NKG2D ligands after transplantation, and that NKG2D may contribute to some graft rejection in immunocompetent hosts.

In humans, allogeneic bone marrow transplantation cures leukemia through the reaction of donor CTL in the graft against the residual leukemic cells. These transferred T cells also mediate graft-versus-host disease (GvHD). The need to prevent this response by strong immunosuppression is the major cause of transplantation failure, due to infection and cancer relapse (Chapter 82). It has been proposed that transplantation with a haploidentical donor (identical at one HLA haplotype and fully mismatched on the other, for example a parent) provides allogeneic NK cells with an HLA haplotype that supplies more KIR ligand than a matched recipient would provide. Hence it would yield a stronger graft-versus-leukemia effect.³⁸ Indeed, mice treated with alloreactive NK cells tolerate 30 times the lethal dose of mismatched bone marrow cells without developing GvHD, and alloreactive NK cells eradicated human acute myeloid leukemia (AML) transplanted into NOD/SCID mice.³⁸ Retrospective studies on AML patients that received haploidentical grafts revealed that transplants with alloreactive NK cells showed better engraftment and GvHD protection, and less relapse.³⁸ The benefit of this protocol is still controversial, as some studies have observed similar effects whereas others have found that KIR ligand mismatch was associated with reduced overall survival.³⁰ The discrepancy may be due to lack of functional assessment of NK-cell alloreactivity, different transplantation

CLINICAL PEARLS

EXPLOITING NK CELLS IN LEUKEMIA THERAPY

- >> Hematopoietic stem cell transplantation requires donor and recipient HLA matching to reduce graft-versus-host disease (GvHD) mediated by transplanted CTL.
- >> Haploidentical donors and recipients (those that share only one HLA haplotype) represent 50% of unrelated transplants and undergo a stronger conditioning regimen to avoid GvHD.
- >> Alloreactive NK cells are present after haploidentical transplant and provide a potent graft-versus-leukemia (GvL) effect in animal models.
- >> Retrospective studies in AML patients show that haploidentical transplantation with alloreactive NK cells have enhanced long-term survival and decreased relapse rates.
- >> Transplantation from NK cell-alloreactive donors controls AML relapse and improves engraftment without causing GvHD.

methods, or the genetic backgrounds of the patients and donors, and thus requires further studies.

■ NK CELLS AND PREGNANCY ■

During pregnancy, maternal (self) and paternal (nonself) antigens are expressed in the embryo and placenta. The reasons why the maternal immune system temporarily tolerates the fetus remain poorly understood. Interestingly, the majority of leukocytes present at the site of implantation are a distinct subset of NK cells known as uterine NK (uNK) cells. Mice deficient in uNK cells show some changes in decidual blood vessels and reduced fertility, supporting a role for these cells, but how they function is unclear.³⁹ uNK cells have low cytotoxic activity and, in addition to IFN- γ and TNF, secrete angiogenic factors such as vascular endothelial growth factor (VEGF-C) and angiopoietin-2.³⁹ This suggests that uNK cells can influence maternal arterial integrity and trophoblast invasion.

uNK cells can recognize HLA-C/E/G on paternal trophoblasts. Recently, it has been found that KIR expression on maternal uNK cells is a key factor in the development of pre-eclampsia (a serious complication of pregnancy in which the fetus receives an inadequate supply of blood due to failure of trophoblast invasion).⁴⁰ Mothers lacking most activating KIR when the fetus possessed HLA-C2 are at a greatly increased risk of pre-eclampsia. Thus, the maternal KIR and trophoblast interaction appears to play a positive physiological role related to placental development, suggesting that too great an inhibition of uNK cells is detrimental to the process.⁴⁰ This has clearly been selected against, as human populations have a reciprocal relationship between certain KIR haplotypes and HLA-C2 frequency.

■ INTERACTIONS OF CTL AND NK CELLS IN THE IMMUNE RESPONSE ■

Although studies of CTL and NK cells in isolation have greatly advanced our understanding of their functions, it is obvious that these immune cells function in a system that depends on numerous interactions between the various cell types at multiple levels (Chapter 2). In the case of cytotoxic cells, these immunomodulatory interactions are becoming increasingly appreciated (Fig. 18.2). In particular, it has become apparent that NK cells and DC interact specifically to promote outcomes such as the maturation of NK cells.²⁶ CTL activation by mature DC is influenced directly by NK cell-derived IFN- γ , and indirectly through the role of NK cells in promoting a Th1 response in CD4 T cells (Chapter 17).

Increasing evidence has emerged to implicate DC-NK cell cross-talk in various aspects of the immune response. DC produce a variety of cytokines that modulate NK-cell behavior, including IL-12, IL-15, IL-18 and IFN- α .²⁶ Interestingly, the outcome of these interactions for the DC depends on its maturity, with immature DC being killed by NK cells whereas mature DC are resistant to lysis. The interactions of mature DC and NK cells would be expected to occur at the site of infection, where DC provide inflammatory stimuli for NK cells. The other site of encounter is the lymph node, where, during an immune reaction, NK cells are recruited by chemokines and interact with mature DC and CD4 T cells to induce a Th1 response. This process requires IFN- γ production from NK cells⁴¹ (Fig. 18.2).

NK-cell and CTL interactions are also important in generating an immune response to tumors that are, in general, poorly immunogenic. DC that are matured *in vitro* by NK cells show strongly enhanced ability to induce Th1 and CTL responses, including cytokine secretion. IFN- γ in particular is very important in the rejection of primary tumors and the formation of CTL memory to tumors. It is also likely that killing by NK cells and CTL provides DC with increased access to tumor antigens and promotes further adaptive immunity. Using DC to harness the helper function of NK cells as well as the cytotoxic functions of both CTL and NK cells offers therapeutic promise and is currently being tested in a variety of cancers.²⁶

■ EVASION OF THE CYTOTOXIC RESPONSE ■

VIRUSES

As one principal function of CTL and NK cells is the control of viral infections, it is not surprising that viruses have evolved a number of strategies to interfere with the host response (Chapter 27). The multiplicity of these evasion strategies indicates that this is an essential step for long-term viral persistence.

These strategies include:

- *Latency.* This involves minimizing viral gene expression and thereby avoiding detection. Examples include HSV in neurons, HIV in T cells, and EBV in B cells.
- *Antigenic variation.* The virus possesses the ability to rapidly mutate its genome and produce escape variants that are no longer visible to CTL. Such mutations were shown for LCMV in mouse and HIV infection in humans.
- *Infection of immune nonaccessible sites.* Such inaccessible sites include infection of the CNS by HSV or rubella.
- *Production of viral defense molecules (immunoevasins).* Many viruses, including adenovirus and EBV, interfere with cytotoxic activity by producing proteins that either hinder Fas or TNF-mediated killing or inhibit the function of antiviral cytokines such as IFN- α/β . A number of viruses, including EBV, produce homologs of anti-apoptotic molecules, such as Bcl2, to inhibit killing by CTL. Various members of the pox virus family have evolved homologs of the naturally occurring IL-18-binding protein that inhibits IL-18 activity and NK-cell function.⁴²
- *Modulation of molecules involved in recognition.* A widely utilized viral strategy to evade the cytotoxic response is to interfere with antigen processing, presentation, or the expression of other molecules required for CTL recognition⁴³ (Chapters 6 and 7). Several viruses, including adenovirus, downregulate MHC class I expression on the cell surface. This can be achieved by a number of mechanisms. For example, adenovirus type 2 E3 protein forms a complex with MHC class I to prevent antigens from being processed; MCMV gp152 protein causes retention of the MHC class I molecules in the Golgi compartment; and CMV proteins US2 and US11 promote the rapid degradation of newly synthesized MHC class I complexes. An alternative approach is to interfere with antigen presentation, either inhibiting the expression of the TAP protein, as is the case for HSV, or producing proteins that are resistant to antigen processing by

the proteasome, such as the EBNA-1 protein of EBV.⁴³ This inhibition strategy is not restricted to MHC class I, as human and mouse CMV express proteins that inhibit the cell surface expression of NKG2D ligands.³²

TUMOR CELLS

Part of the evidence that CTL and NK cells function to control malignant cells comes from the effort the tumor cell will go to avoid cytotoxic activity. Conversely, promoting the cytotoxic response either through specific tumor antigens or through polyclonal stimulation remains one of the most actively pursued strategies in cancer therapy.

Tumors evade cytotoxic function in a number of ways:

- *Downregulation or loss of MHC class I expression.* This strategy is common in solid tumors, including metastatic melanoma and breast cancer, where MHC class I downregulation accounts for up to 50% of samples.⁴⁴ MHC class I loss is also induced by mutations in the gene encoding β_2 -microglobulin or transcription factors that regulate its expression. In contrast, MHC class I downregulation is associated with changes in the regulatory mechanisms controlling antigen presentation, and can often be corrected by treatment with cytokines such as IFN- γ .⁴⁴
- *Antigenic mutation.* Tumors can also avoid CTL activity by antigenic loss. This strategy takes the form of silencing or mutating epitopes that are particularly immunogenic to CTL (Chapter 79). This phenomenon has been shown most clearly for the loss of immunogenicity of serially transferred tumor cell lines in the mouse. In human malignancies, tumor antigens such as MART-1 have been found to be lost in metastatic melanoma independent of treatment.⁴⁵
- *Immune modulation by tumor-produced factors.* Tumors express a variety of factors that can modulate the immune response, including FasL, which protects the tumor by inducing apoptosis in activated Fas-expressing CTL. This model is not universally accepted and a role for FasL in inducing the expression of inflammatory cytokines is also possible. Tumors are also known to express TGF- β , which acts on CTL and NK cells to inhibit the expression of effector molecules such as perforin and granzymes. TGF- β also acts on NK cells to downregulate the expression of NKG2D. In addition, tumors can produce soluble decoy ligands such as MIC, which suppresses NKG2D function.²⁰

Host defenses at mucosal surfaces

Kohtaro Fujihashi, Prosper N. Boyaka,
Jerry R. McGhee

19

Mammals have evolved a sophisticated network of cells and molecules that serve to maintain homeostasis on exposed mucosal surfaces. It is noteworthy that this system, termed mucosa-associated lymphoreticular tissue (MALT), is anatomically and functionally distinct from its blood-borne counterpart and is strategically located at the portals by which most microorganisms enter the body. The development of this specific branch of the immune system alongside and separate from the peripheral immune system may have been necessitated by the size of the mucosal surfaces, which cover an area of ~400 m² in the adult human, as well as the large number of exogenous antigens to which these surfaces are exposed.

■ THE INNATE MUCOSAL DEFENSE SYSTEM ■

The innate defense of the mucosa includes the physical barrier provided by epithelial cells, the movement of the epithelial cilia, the production of mucus by goblet cells, the secretion of molecules with innate antibacterial activity, and the cytolytic activity of NK cells (Fig. 19.1). These innate mechanisms provide a first line of defense against exogenous antigens and invading pathogens.

PHYSICAL BARRIER PROVIDED BY EPITHELIAL CELLS

Mucosal surfaces are covered by a layer of epithelial cells that prevent the entry of exogenous antigens into the host while permitting the absorption of nutrients.¹ In the gastrointestinal (GI) tract, the barrier effect of tightly joined epithelial cells, termed enterocytes, is facilitated by the blanket of mucus that covers these cells. Mucus is secreted by goblet cells and consists of glycoproteins of various molecular sizes that tend to interfere with the attachment of microorganisms. Damaged or infected enterocytes are replaced by crypt epithelial cells, which differentiate into enterocytes as they migrate towards the desquamation zone at the villus tip. Multilayered squamous epithelial cells cover the epithelia of other mucosal surfaces, including the oral cavity, the pharynx, the tonsils, the

urethra and the vagina. These epithelia lack tight junctions. They secrete a glycoprotein mucus that coats the intercellular space between the lower stratified layers. Additional barrier effects are provided by secretory IgA (SIgA), and by the renewal of exposed epithelial cell layers by cells from subjacent layers.

DEFENSINS AND OTHER MUCOSAL ANTIMICROBIAL PEPTIDES

Cells of the epithelium produce antimicrobial β -sheet proteins termed defensins, that range between 30 and 40 amino acids in length and which exhibit antimicrobial effects similar to those of antibiotics. Based upon their structure, defensins can be grouped into two distinct categories, α and β . α -defensins, which contain two contiguous cysteine residues, are smaller than β -defensins, whose cysteine residues are separated by six amino acids. In the crypt regions of villi, Paneth cells produce α -defensin granules that can be secreted into the lumen of the small intestine. α -defensins are also secreted by tracheal epithelial cells. They are homologous to peptides that function as mediators of nonoxidative microbial cell killing in neutrophils (termed human neutrophil peptides, or HNP).² β -defensins, such as human β -defensin 1 (HBD-1), are expressed in the epithelial cells of the oral mucosa, trachea, bronchi, mammary glands, and salivary glands. The activity of mucosal defensins also applies to viruses. Although mechanisms that control the activation of defensins are poorly understood, inflammatory cytokines such as interleukin-1 (IL-1), tumor necrosis factor- α (TNF- α) and bacterial lipopolysaccharide (LPS) play a role in their induction.

Other potent antimicrobial products of the epithelium include lactoferrin, lysozyme, the peroxidases, secretory phospholipase A₂, and cathelin-associated peptides. Some are secreted by intestinal Paneth cells, and all are produced by polymorphonuclear neutrophils (PMNs). Lactoferrin, a member of the transferrin family, is found in exocrine secretions such as milk. High concentrations of lysozyme (1209–1325 μ g/mL) are found in tears and other secretions, such as saliva, colostrum, serum and urine.

Human milk contains lysozyme in concentrations ranging from 20 to 245 μ g/mL, depending on the lactation period. It also contains at least two peroxidases. Milk leukocytes produce myeloperoxidase (MPO) and

mammary gland cells produce human lactoperoxidase (hLPO). Both peroxidases display properties similar to those of human salivary peroxidases (hSPO). Secretory phospholipase A2 (S-PLA2) is released by Paneth cells upon exposure to cholinergic agonists, bacteria or LPS. Secretory leukocyte protease inhibitor (SLPI) is found in human saliva, nasal secretions, tears, cervical mucus and seminal fluid. It is believed to be responsible for the anti-HIV properties of external secretions.

Fig. 19.1 Innate mucosal host defense factors. A thick coat of mucus prevents penetration of macromolecules and potential pathogens. The epithelial cell barrier is connected via tight junctions and contains both $\alpha\beta$ and $\gamma\delta$ intraepithelial lymphocytes (IELs). The crypt regions contain Paneth cells, which produce cryptidins (α -defensins). The β -defensins are products of epithelial cells and form a defensin network. Other innate factors, such as lysozyme, lactoperoxidase, lactoferrin and phospholipases, also serve in antimicrobial defense.

KEY CONCEPTS

INNATE DEFENSES OF THE MUCOSAL IMMUNE SYSTEM

The innate defenses of the mucosal immune system provide a first line of defense against exogenous antigens and invading pathogens. These defenses include:

- >> Physical barriers: the epithelium, the epithelial cilia, goblet cell mucus production
- >> Mucosal antibacterial molecules: Paneth cell production of α -defensins in the small intestine; epithelial cell production of β -defensins in the oral mucosa, trachea, bronchi, mammary glands and salivary glands; lactoferrin, lysozyme, lactoperoxidase, and secretory leukocyte protease inhibitor (SLPI)
- >> Cellular innate immunity: mucosal natural killer (NK) cells

MUCOSAL NATURAL KILLER CELLS

Natural killer (NK) cells are found in both the lamina propria and the intraepithelial compartment, where they appear as large granular lymphocytes. Nonspecific recruitment of cytotoxic effector cells into the intestinal mucosa occurs in either antigen-primed or virus-infected mice. As NK cells secrete IFN- γ and IL-4 after infection, they may influence the development of effector T cells as well (Chapter 18).

A COMMON MUCOSAL IMMUNE SYSTEM

Higher mammals have developed an organized secondary lymphoid tissue system in the GI and upper respiratory tracts. The gut-associated lymphoreticular tissues (GALT) include Peyer's patches (PPs), the appendix, and solitary lymphoid nodules in the GI tract. The tonsils and adenoids comprise the nasal-associated lymphoreticular tissues (NALT). Experimental animals such as rabbits, rats and guinea pigs exhibit organized bronchus-associated lymphoreticular tissues (BALT) that rarely occur in human airway branches.¹ Together, GALT and NALT in healthy humans, and GALT, BALT and NALT in experimental species, are termed mucosa-associated lymphoreticular tissue, or MALT.

The vast areas of the mucosal immune system characterized by diffuse collections of lymphoid cells are termed the effector tissues. These include the interstitial tissues of the mammary, lacrimal, salivary, sweat and all other exocrine glands, as well as the lamina propria and the epithelium of the GI tract. The lamina propria areas of the upper respiratory and genitourinary tracts are also lymphoid effector sites. MALT is connected with effector sites through the migratory patterns of lymphoid cells.

KEY CONCEPTS

THE COMMON MUCOSAL IMMUNE SYSTEM

The mucosa-associated lymphoreticular tissues (MALT) comprise discrete and diffuse collections of lymphoid tissues that share distinctive features, including a unique type of epithelium, a distinct architecture, a unique set of antigen-presenting cells (APCs), and B cells where switching to IgA predominates. The involved tissues include:

- >> The gut-associated lymphoreticular tissues (GALT): Peyer's patches, the appendix, and solitary lymphoid nodules in the GI tract
- >> The nasal-associated lymphoreticular tissues (NALT): the tonsils and adenoids
- >> The effector tissues: the interstitial tissues of the mammary, lacrimal, salivary, sweat and all other exocrine glands; the lamina propria and the epithelium of the GI tract; and the lamina propria areas of the upper respiratory and genitourinary tracts

MALT AS AN INDUCTIVE SITE

MALT differs from systemic lymphoid tissues owing to the presence of a unique type of epithelium for antigen uptake. Its features include a characteristic architecture; antigen-presenting cells (APCs), such as dendritic cells that differ from APCs in spleen; and B-cell areas with germinal centers where switches of IgM to IgA bearing B cells predominate. The columnar epithelium that covers MALT is infiltrated with lymphocytes and APCs, leading to the term follicle-associated epithelium (FAE). Lacking goblet cells, the FAE is covered with far less mucus than normal enterocytes. Soluble and particulate luminal antigens are taken up by microfold (M) cells and are delivered to adjacent APCs. M cells have been described in PPs, the appendix and tonsils, and represent 10–15% of cells within the FAE.³ M cells are also found in isolated lymphoid follicles (ILFs) and at the tips of the villus, where they are termed villous M cells.⁴ The microvilli of these cells, which are less dense than those of adjacent enterocytes (Fig. 19.2), offer a portal of entry into the MALT. The M cell is often identified by an invagination of the basolateral membrane into a ‘pocket’ normally occupied by lymphocytes and APCs (Fig. 19.3).

M cells appear ideal for antigen uptake owing to a well developed microvesicle system that contains endosomes. However, it remains unclear whether M cells act as classic APCs. M cells also provide a portal of entry for some invasive pathogens, such as invasive strains of *Salmonella typhimurium*, but not for noninvasive strains of *S. typhimurium* and reoviruses.

GUT-ASSOCIATED LYMPHORETICULAR TISSUES (GALT)

Each PP contains a dome region that is positioned under the FAE. This dome region is populated by T cells, B cells, macrophages (M ϕ) and dendritic cells (DC), and include follicles that contain germinal centers. The presence of all three major APC types in the dome, i.e., memory B cells, M ϕ and DCs, makes it likely that antigen uptake occurs immediately after release from M cells (Fig. 19.4A). M cell pockets in Peyer’s patches contain approximately equal numbers of T and B cells, but fewer macrophages. Approximately 75% of the T cells are T helper (Th) cells.

GALT B cell follicles differ from those in peripheral lymph nodes and spleen in that they are enriched for IgA-bearing B cells.¹ Thus, germinal centers in MALT are thought to be the major sites for B cell μ to α switching (Chapters 4 and 8). The interfollicular regions of PPs contain the high endothelial venules (HEVs), which represent the major point of entry for T and B cells, as well as an interdigitating network of dendritic cells and mature T cells. Both CD4 and CD8 TCR $\alpha\beta$ T cells are found in these interfollicular regions, with CD4 cells representing the predominant phenotype. Both naïve and memory T cells are present in PPs, with one-third in cell cycle (Fig. 19.4, Table 19.1).

The structurally and functionally related cytokines, lymphotoxin- α (LT- α), lymphotoxin- β (LT- β), and TNF- α (Chapter 10), are critical for lymphoid organogenesis. LT- $\alpha^{-/-}$ mice are markedly deficient in secondary lymph nodes,⁵ whereas LT- $\beta^{-/-}$ mice have mesenteric and cervical lymph nodes, but lack peripheral lymph nodes and PPs. TNF-RI $^{-/-}$ mice are characterized by an absent or abnormal PP structure, whereas TNF- $\alpha^{-/-}$ mice exhibit normal patches.⁵ In

humans, PPs develop during prenatal life, a situation also seen in sheep, pigs, dogs, and horses. ILF formation occurs postnatally in response to luminal stimuli, including the normal bacterial flora.⁶ Mature ILFs contain mostly conventional B cells and small numbers of CD4 T cells.⁶

Fig. 19.2 The microfold (M) cell. A scanning electron micrograph of an M cell with adjacent enterocytes. The M cell has selectively bound *E. coli* 0157. Note that a thick brush border is lacking, facilitating the binding and uptake of microparticles. (Courtesy of Dr Tatsuo Yamamoto, Niigata University.)

Fig. 19.3 Microanatomical features of M cells. The M cell forms a ‘pocket’ containing memory lymphocytes. It actively pinocytoses soluble antigens and phagocytoses particulates such as viruses, bacteria and microspheres. (Courtesy of Dr Svein Steinsvoll, University of Oslo.)

Fig. 19.4 Structural features and cellular components of gut-associated lymphoreticular tissues (GALT). **(A)** The dome region is covered by the follicle-associated epithelium (FAE) with its characteristic microfold or M cells. Major features of the dome include M cells with lymphocyte pockets, scattered plasma cells and immature dendritic cells (DCs). The B-cell area contains five or more germinal centers with high frequencies of surface IgA⁺ B cells. The adjacent T-cell area contains mature interdigitating DCs and precursors of CD4 Th and CD8 CTLs. **(B)** Structural features and cellular characteristics of mucosal effector sites. The lamina propria is equally populated by B1 and B2 cells, both of which differentiate into IgA⁺ plasma cells. Note that memory B and T lymphocytes are also both present in this compartment. Although intraepithelial lymphocytes (IELs) in human are mainly TCRαβ⁺, significant numbers of TCRγδ⁺ T cells are also found in this compartment.

Table 19.1 Major T-cell subpopulations associated with Peyer's patches

T-cell phenotype	Percentage of total T cells
CD3 $\alpha\beta$ TCR	95–97
CD3 ⁺ $\gamma\delta$ TCR ⁺	3–5
CD3 ⁺ , CD4 ⁺ (precursors of Th)	65–70
CD3 ⁺ , CD8 ⁺ (precursors of CTLs)	30–35
Naïve (CD45RB ^{Hi})	50–60
Memory (RB ^{Lo} , RO ^{Hi})	40–50
Blasts (in cell cycle)	30–35

NASAL-ASSOCIATED LYMPHORETICULAR TISSUES (NALT)

Strategically positioned at the entry of the respiratory as well as the digestive tracts are the accumulations of lymphoid tissues that comprise the palatine, lingual and nasopharyngeal tonsils, which collectively form Waldeyer's ring. These tissues resemble both lymph nodes and PPs, including an FAE with M cells in the tonsillar crypts that is essential for selective antigen uptake (Fig. 19.3). Germinal centers containing B and T cells, plasma cells and professional APCs are also present. Tonsillar tissues may serve as a source of IgA plasma cell precursors found in the upper aerodigestive tracts, as well as an inductive site for more generalized mucosal and systemic immune responses.⁷ Induction through the nasal cavity may well exceed that induced by oral immunization. When viral and bacterial antigens are introduced into the nasal cavity, usually along with mucosal adjuvants such as cholera toxin (CT) and/or its B subunit (CT-B), optimal immune responses are induced in external secretions, such as saliva and, surprisingly, in secretions of the female genital tract.¹

The LT $\alpha_1\beta_2$ signaling pathway appears to be essential for the maintenance, but not the initiation, of NALT organogenesis.⁴ Thus, despite reductions in the size and the numbers of DCs and FDCs present, the NALT was still detected in LT- $\alpha^{-/-}$ and LT- $\beta^{-/-}$ mice, although the size of this tissue was reduced. Newborn mice did not contain any NALT structure in the nasal cavity, demonstrating that NALT develops postnatally. Signaling via the IL-7/IL-7R and the L-selectin/PNAd adhesion molecules plays an important part in the organization of NALT.⁴ Thus cytokine signaling cascades, and in particular the LT $\alpha_1\beta_2$ -LT β R signaling pathway, are essential for the maintenance of NALT architecture.

OTHER POTENTIAL SITES FOR MUCOSAL INDUCTION OF AN IMMUNE RESPONSE

The follicular structures analogous to PPs found in the large intestine and especially in the rectum, which are known as rectal-associated lymphoreticular tissues (RALT), are another IgA-inductive site and a source of IgA plasma cell precursors. Unlike most other mucosal tissues, the lamina propria of the large intestine is characterized by a predominance of IgA2- versus IgA1- producing cells.¹ This preference for IgA2 also occurs in the female genital mucosal tissues (e.g., uterus, cervix, fallopian tubes and vagina), suggesting lymphoid trafficking between these tissues. Indeed, intrarectal immunization of Rhesus macaques with simian immunodeficiency virus (SIV) induced both T- and B-cell-mediated immune responses, including

the induction of anti-SIV Abs in rectal washes and in genital secretions.⁸ Rectal immunization with a bacterial vaccine (*Salmonella typhi* Ty21a) was shown to induce specific Abs not only at the site of immunization, but also in saliva, suggesting even more extensive trafficking.⁹

LYMPHOCYTE HOMING INTO MUCOSAL COMPARTMENTS

There is a direct route for B-cell migration between PPs and GI lamina propria (Fig. 19.4B). Indeed, the mesenteric lymph nodes of orally immunized animals can repopulate the lamina propria of gut, mammary glands, lacrimal glands, and salivary glands with antigen-specific IgA plasma cells (Fig. 19.4B),¹ pointing to the existence of a 'common' mucosal immune system. This concept has undergone further refinement, as studies now show that the migration of cells into and from NALT adheres to rules different from those for cell migration into and from GALT and the GI tract.

LYMPHOCYTE HOMING IN THE GI TRACT

Naïve lymphocytes enter mucosal or systemic lymphoid tissues from the blood through specialized high endothelial venules (HEV), which consist of cuboidal endothelial cells (Fig. 19.5A). In GALT, HEV are present in the interfollicular zones, which are rich in T cells.¹⁰ In effector sites such as the lamina propria of the GI tract, the endothelial venules are less pronounced and tend to occur near villus crypt regions (Fig. 19.5B). Mucosal addressin cell adhesion molecule-1 (MAdCAM-1) is the most important addressin expressed by PP HEV or lamina propria venules (LPV) (Chapter 12). Peripheral lymph node addressin (PNAd) and vascular cell adhesion molecule (VCAM-1) are the principal addressins expressed by peripheral lymph node and skin HEV, respectively.

The major homing receptors expressed by lymphocytes are the integrins, a large class of molecules characterized by a heterodimeric structure of α and β chains (Chapter 12). In general, the type of homing receptor is determined by the integrin expressed with the α_4 chain; the β_1 -integrin characterizes the homing receptor for the skin, whereas the β_7 -integrin characterizes the receptor for the gut. The pairing of α_4 with β_7 is thus responsible for lymphocyte binding to the MAdCAM-1 that is expressed on HEVs in PPs and GI tract LPVs (Fig. 19.5).¹¹

The C-type lectins L-, E- and P-selectin (Chapter 12) also serve as homing receptors. L-selectin has a high affinity for carbohydrate-decorated

Fig. 19.5 Structural features and lymphocyte homing into GALT. **(A)** High endothelial venules (HEV) occur in T-cell areas and express the ligands MAdCAM-1, ICAM-1 and CCR7. Naive T and B cells, which are L-selectin⁺, $\alpha_4\beta_7$ ⁺ and LFA-1⁺, all participate in rolling, binding activation, arrest and diapedesis in the HEV (Chapter 12). On the other hand, memory B cells and T cells express $\alpha_4\beta_7$ ⁺⁺⁺ and LFA-1⁺⁺⁺ (see text for details). **(B)** Lymphocyte receptors and addressin ligands involved in homing into mucosal effector sites of the GI tract. The majority of B and T cells exhibit a memory phenotype with co-expression of $\alpha_4\beta_7$ ⁺⁺⁺ and LFA-1⁺⁺. The expression of the G protein-coupled receptor CCR-9 allows the homing steps that occur on lamina propria venules (see text for details).

PNAd, which is of central importance in peripheral lymph node homing of B and T cells. L-selectin can also bind to carbohydrate-decorated MAdCAM-1 and is an important initial receptor for homing into GALT HEVs.

Chemokines are also involved in lymphocyte homing, with different chemokine-receptor pairs controlling migration into different lymphoid tissues (Chapter 11). For example, loss of secondary lymphoid

tissue chemokine (SLC) results in lack of naive T-cell or dendritic-cell migration into spleen or Peyer's patches. CCR4, which responds to the thymus activation-regulated chemokine (TARC) and macrophage-derived chemokine (MDC), mediates the arrest of skin-homing T cells, but does not affect $\alpha_4\beta_7$ ^{hi} T-cell migration in the GI tract. Conversely, memory $\alpha_4\beta_7$ ^{hi} T cells that express the receptor for thymus-expressed chemokine (TECK), CC9, migrate into the lamina

propria of the GI tract. Both human $\alpha_E\beta_7^+$ and $\alpha_4\beta_7^{\text{hi}}$ CD8 T cells express CCR9, suggesting that TECK-CCR9 is also involved in lymphocyte homing and the arrest of IELs in the GI tract epithelium (Fig. 19.4).

Peyer's patches and GALT contain both naïve and memory T- and B-cell subsets, whereas lamina propria consists of memory T and B cells and terminally differentiated plasma cells (Table 19.1 and Fig. 19.4). Naïve B cells and T cells destined for GALT express L-selectin, moderate levels of $\alpha_4\beta_7$ ($\alpha_4\beta_7^+$) and LFA-1. Memory lymphocytes destined for lamina propria express higher levels of $\alpha_4\beta_7$ ($\alpha_4\beta_7^{\text{hi}}$) and lack L-selectin. Initial rolling is dependent on $\alpha_4\beta_7$ interaction with LPV MAdCAM-1. Activation-dependent binding and extravasation also require LFA-1-ICAM binding. $\alpha_4\beta_7$ also mediates binding to E-cadherin, and CCR9 expression may result in activation-dependent entry into the epithelial cell compartment.

Migration out of the lymph nodes also appears to depend on addressins. Cryosections of human tissues have revealed naïve T and B cells in HEV that express both L-selectin and $\alpha_4\beta_7$, whereas memory T and B cells in efferent lymphatics express $\alpha_4\beta_7$ but not L-selectin. The majority of cells in mesenteric lymph nodes, including B-cell blasts, tend to be of the memory phenotype and are $\alpha_4\beta_7^{\text{hi}}$, L-selectin^{low}. Ig-containing B-cell blasts also express high levels of $\alpha_4\beta_7$.

The separation of naïve and memory T and B cells for entry into GALT HEV or LPV has important implications in vaccine development. Recent studies offer strong evidence that peripheral blood mononuclear cells, which are assumed to home to systemic lymphoid tissues, are also destined for mucosal effector sites in the GI tract. For example, an oral cholera vaccine elicited transient IgA antibody-forming cells (AFC) in blood and subsequent IgA anticholera toxin AFC in duodenal tissues.¹² In a separate study, most peripheral blood AFC induced after parenteral immunization were L-selectin⁺, whereas those induced after oral and rectal immunization were predominantly $\alpha_4\beta_7^+$ AFCs.¹³ In this latter study most of the AFCs produced IgA, but some also expressed IgG. Interestingly, after nasal immunization AFC expressed both L-selectin and $\alpha_4\beta_7$ homing receptors. These results suggest that enteric immunization of GALT can trigger the appearance of $\alpha_4\beta_7^+$ memory IgA and IgG B cells, which can then migrate into the bloodstream.

LYMPHOCYTE HOMING IN NALT AND LUNG-ASSOCIATED TISSUES

Unlike PP HEVs, which are found in T-cell zones, murine NALT HEV are found in B-cell zones and express PNAd either alone or associated with MAdCAM-1. Moreover, anti-L-selectin Abs – but not anti-MAdCAM-1 Abs – block the binding of naïve lymphocytes to NALT HEV, suggesting a predominant role for L-selectin and PNAd in the binding of naïve lymphocytes to these HEV.¹⁴

During pulmonary immune responses, induction of VCAM-1, E-selectin and P-selectin in the pulmonary vasculature is matched by increased expression of P-selectin ligand on peripheral blood CD4 and CD8 T cells.¹⁵ The number of cells that express P-selectin ligand in the blood subsequently declines as the cells accumulate in the bronchoalveolar lavage fluid. Very late antigen (VLA-4) appears to be involved, as migration of VLA-4⁺ T cells into bronchoalveolar fluid is impaired following treatment with anti- α_4 Ab. Antigen-specific L-selectin^{low} cytotoxic lymphocyte (CTL) effectors also accumulate in the lung.

A study of cell homing in the NALT showed that following systemic immunization most effector B cells expressed L-selectin, with only few cells expressing $\alpha_4\beta_7$, whereas after enteric (oral or rectal) immunization the opposite held true.¹⁶ Effector B cells induced by intranasal immunization display a more promiscuous pattern of adhesion molecules, with a large majority expressing both L-selectin and $\alpha_4\beta_7$.

THE COMMON MUCOSAL IMMUNE SYSTEM REVISITED

The existence of a common mucosal immune system has become almost a matter of dogma, and so the homing pattern that has been elucidated in the GI tract after immunization of GALT has been taken to be the model for all mucosal immune sites. However, the more recent studies summarized above suggest instead that the specific set of homing receptors and ligand addressins expressed in the GI tract are absent in NALT or associated lymph nodes. The failure of tonsillar cells to demonstrate selective $\alpha_4\beta_7$ expression, and the lack of MAdCAM-1 expression on tonsil HEVs, makes it likely that gut homing does not extend to human NALT and associated lymph nodes. It remains possible, and even likely, that memory T and B cells from the gut may enter NALT for additional priming and reprogramming of homing receptors. Likewise, memory T and B cells induced in NALT may traffic to lung and genitourinary tract tissues, as well as to the GI tract. Thus, the rules for the homing of naïve T- and B-cell precursors into NALT need to be more clearly defined.

INDUCTION OF MUCOSAL IMMUNITY

Immune responses expressed in mucosal tissues are typified by secretory immunoglobulin A (S-IgA) Abs, which constitute the predominant Ig isotype in external secretions. The resistance of S-IgA to endogenous proteases makes Abs of this isotype uniquely suited to protect mucosal surfaces. The development of mucosal immunity requires T cells, including CD4 T helper (Th) cell subsets, CD8 CTLs, and other T-cell subsets. B-cell commitment (μ to α switching) and B-/T-cell interactions are of central importance, resulting in the induction of plasma cells producing pIgA. Cytokines produced by CD4 and CD8 T cell subsets, and by dendritic cells (DCs), macrophages (M ϕ) and B cells, as well as by non-classic APCs (e.g., epithelial cells), all contribute to the induction of a normal mucosal immune response.

MUCOSAL ANTIGEN-PRESENTING CELLS

Large macromolecules are taken up by M cells in the GI tract. N418⁺, 2A1⁺, NLDC-145⁺, M342⁺ DCs form a dense layer of cells in the sub-epithelial dome (SED) just beneath the follicle epithelium, where CD4, but not CD8, T cells can be found.¹⁷ Another subset of DCs, N418⁺, 2A1⁺, NLDC-145⁺ and M342⁺, populates the interfollicular T-cell regions where both CD4 and CD8 T cells reside. DCs in the dome region are immature, highly endocytic, and express low levels of MHC and B7 molecules. DCs in the T-cell area are mature, with low endocytic activity and high levels of MHC class I and II molecules, and B7 molecule expression. Antigen taken up by M cells appears to be first endocytosed in the dome region by immature DCs, which then migrate to

Fig. 19.6 T-helper cell subset development. The cellular and cytokine environment induces Th0 cells to develop into either Th1 or Th2 subsets. APCs produce IL-12 in response to microbial assault and, together with IFN- γ produced by NK cells, induce mature Th1 cells. Th1 cells express select chemokine receptors and, through IFN- γ synthesis, activate M ϕ and induce B cells to produce opsonizing Abs. Other cells, such as NK1.1 and mast cells, respond to antigen/allergen with IL-4, which induces Th0 to Th2 switching. Th2 cells produce IL-4, IL-5, IL-6, IL-10, IL-9 and IL-13, which help regulate mucosal S-IgA Ab responses.

T-cell interfollicular areas where maturation occurs (Fig. 19.4A). DCs are also found in NALT such as human tonsils and lung, where they play the same role as in the GALT.

Intestinal epithelial cells (IECs) express MHC class II molecules and present peptides to primed CD4 and CD8 T cells. However, it is still unclear whether IECs can process antigen or if the MHC class II molecules on these cells only serve as receptors for predigested peptides that result from enzymatic lysis in the stomach. Human and murine IECs also express CD1d, a nonclassic MHC class I molecule that is also found on DCs and M ϕ and which appears to be involved in the presentation of lipid and glycolipid antigens.

CD4 TH CELL SUBSETS IN MUCOSAL IMMUNITY

Th cell subsets are classified as either Th1 or Th2 according to the pattern of cytokines produced (Chapter 17). Th1 cells selectively produce IL-2, IFN- γ , LT- α , LT- β and TNF- α , whereas Th2 cells produce IL-4, IL-5, IL-6, IL-9, IL-10 and IL-13 (Fig. 19.6). The recently described Th17 produce IL-17, both Th1 and Th2 cells develop from naïve CD4 T cells through the same T-cell precursor (Th0) phase (Chapter 9). IL-2 is produced by Th0 cells upon antigen exposure and serves as an important growth factor. IL-12 induces NK cells to produce IFN- γ which, together with IL-12, triggers Th0 cells to differentiate along the Th1 pathway. Murine Th1-type responses are associated with the development of cell-mediated immunity, as manifested by delayed-type hypersensitivity (DTH) and by B-cell responses with a characteristic IgG Ab subclass (IgG2a) pattern. The Th2 cell subset is an effective

helper phenotype for supporting the production of the IgA isotype, in addition to IgG1, IgG2b and IgE responses in the mouse system. IFN- γ produced by Th1 cells inhibits both Th2 cell proliferation and B-cell isotype switching stimulated by IL-4. Likewise, Th2 cells regulate Th1 cell effects by secreting IL-10, which inhibits IFN- γ secretion by Th1 cells. This decreased IFN- γ production allows the development of Th2-type cells.

It is now accepted that polarized T-cell responses occur in humans as well. Thus, human Th1 and Th2 cells reciprocally regulate the development of the opposite subset through IFN- γ and IL-4 secretion, respectively (Fig. 19.6). Antigen-specific IgG subclass responses in patients with Lyme borreliosis, a pathology known to induce Th1 cells and strong IFN- γ responses, consisted of IgG1 and IgG3 C-fixing Abs with low IgG2 and undetectable IgG4 Ab levels.¹⁸ Despite the differences between murine and human systems, these observations suggest that IL-4 and IFN- γ control respectively IgG1 and IgG2a in the mouse, and IgG4 and IgG1 subclasses in humans in an analogous manner (Fig. 19.6).

Adhesion molecules and chemokines also provide distinct address codes for the migration of Th1 and Th2 cells to different sites. Th1 cells express functional ligands for E- and P-selectins that allow these cells to migrate to sites of inflammation.¹⁹ *In vitro*, Th1 and Th2 cells also express distinct patterns of chemokine receptors (Chapter 11). CCR5 and the CXC chemokine receptors CXCR3 and CXCR5 are preferentially expressed by Th1 cell clones, whereas CCR4, and to a lesser extent CCR3, are expressed by Th2 clones (Fig. 19.6).

CYTOKINES IN MUCOSAL IMMUNITY

B-cell isotype switching

Isotype switching is preceded by transcriptional activation of the isotype in question (Chapter 4). Two major cytokines, IL-4 and TGF- β , induce surface IgM-positive (sIgM⁺) B cells to switch to downstream isotypes, including IgE and IgA (Fig. 19.7). The addition of TGF- β 1 to LPS-triggered mouse B-cell cultures can lead to increased IgA synthesis, an effect that can be enhanced by IL-2 or IL-5. TGF- β 1 can also induce sIgM⁺ to sIgA⁺ B-cell switches. Anti-CD40 stimulation of tonsillar B cells, together with TGF- β 1 in the presence of IL-10, further stimulates IgA synthesis.¹ C α 1 transcripts can also be induced by B-cell mitogen plus TGF- β , and C α 2 transcripts can be induced by TGF- β together with IL-10, perhaps implying that switches to IgA2 are more T cell- and Th2-cytokine dependent. TGF- β 1 gene knockout (TGF- β 1^{-/-}) mice exhibit low levels of IgA plasma cells in effector sites and of S-IgA in external secretions,¹ providing further evidence that TGF- β 1 can be an important factor in μ to α switching (Fig. 19.7).

IgA plasma cell differentiation

Two Th2 cytokines, IL-5 and IL-6, are of particular importance for inducing sIgA⁺ B cells to differentiate into IgA-producing plasma cells.²⁰ In this regard, IL-6 induced strikingly high IgA responses in vitro in both murine and human systems.

VACCINE DEVELOPMENT AND MUCOSAL IMMUNE RESPONSES

Mucosal immune responses include a major B-cell component that is characterized by secretory IgA (S-IgA) Ab, as well as Th cell and CTL responses. These responses can be induced by pathogens triggering the organized mucosal inductive sites. Effective protection against strong mucosal pathogens requires prophylactic immune responses that can be achieved by mucosal vaccines. In contrast to systemic vaccines, those administered via mucosal routes can trigger both mucosal immune responses as a first line of defense at the portal of pathogen entry, and systemic immune responses that neutralize pathogens that have penetrated that barrier. Because it is now well accepted that Th1-type responses result in B- and T-cell responses distinct from those induced by Th2-type cells, mucosal adjuvants, vectors and delivery systems are being developed for vaccines that can specifically induce Th1- or Th2-type responses.

HELPER T-CELL SUBSETS IN MUCOSAL IMMUNE RESPONSES TO VACCINES

Two classes of mucosal vaccine delivery system have helped to define the role of mucosal adjuvants and recombinant vectors for the induction of Th cell subsets that support mucosal S-IgA and serum Ab responses. In mouse, the mucosal adjuvant cholera toxin (CT) has been shown to promote mucosal S-IgA as well as serum anti-vaccine and anti-CT-B subunit

Fig. 19.7 The gene organization, switching to IgA and IgA plasma cell formation in mice and humans. Production of IgA is regulated at several steps that may become dysfunctional and result in IgA deficiency. These steps include T switch (Tsw) cells, switch cytokines (e.g. TGF- β), as well as Th cell subsets and cytokines that promote IgA synthesis. In the lower panel various mouse gene knockouts are shown which display either impaired or blocked mucosal IgA responses. Individual knockout mouse studies are described in the text. From McGhee JR, Kiyono H. The mucosal immune system. In: Paul WE, ed. Fundamental immunology. Philadelphia, Lippincott-Raven, 1999; 909.

CLINICAL RELEVANCE

MUCOSAL ADJUVANTS AND DELIVERY SYSTEMS FOR THE INDUCTION OF TARGETED IMMUNITY

A variety of adjuvants and delivery systems are being developed with the aim of targeting immunity to the mucosal immune system. These include:

- >> Genetically engineered bacterial enterotoxins: e.g., cholera toxin (CT) and heat-labile (LT) toxin from *Escherichia coli*
- >> Immunostimulatory DNA sequences: These sequences typically contain a transcription unit designed to express the antigen in question that is coupled to an adjuvant/mitogen unit, such as CpG motifs
- >> Mucosal cytokines and innate factors as adjuvants: Mucosal delivery of specific cytokines or innate factors can reduce the risk of adverse systemic effects while targeting the immune response to the mucosa
- >> Transgenic plants: Plants, such as bananas or rice, can be engineered to express both B- and T-cell antigen epitopes, providing a simple delivery system for oral vaccination or oral tolerance induction.

(CT-B) Ab (IgG1 and IgE) responses associated with CD4 Th2 cells.²¹ Conversely, recombinant *Salmonella typhimurium* BRD 847 (*aroA*-, *aroD*-) expressing the C fragment of tetanus toxin has been shown to be an excellent oral vaccine vector for the induction of Th1-type responses with brisk mucosal S-IgA as well as serum Ab (IgG2a) responses.²¹

NEW MUCOSAL ADJUVANTS AND DELIVERY SYSTEMS FOR THE INDUCTION OF TARGETED IMMUNITY

Bacterial enterotoxins and their nontoxic derivatives

Two bacterial enterotoxins (i.e., cholera toxin (CT) and heat-labile toxin (LT) from *Escherichia coli*) are now established as effective for the induction of both mucosal and systemic immunity to co-administered protein antigens. Cholera toxin consists of two structurally and functionally separate A and B subunits (Fig. 19.8). The B subunit of CT (CT-B) binds to GM1 gangliosides, which on epithelia allows the A subunit to reach the cytosol of target cells, where it acts to elevate cAMP, thereby promoting secretion of water and chloride ions into the intestinal lumen. The labile toxin (LT) from *E. coli* is closely related to CT and binds to GM1 gangliosides as well. LT also binds GM2 and asialo-GM1 gangliosides. In order to circumvent toxicity, mutant CT (mCT) and LT (mLT) molecules have been generated by site-directed mutagenesis (Fig. 19.8), wherein single amino acid substitutions have been made in the active site of the A subunit of CT or LT, or in the protease-sensitive loop of LT. The levels of antigen-specific serum IgG and S-IgA Abs induced by these mutants are comparable to those induced by wild-type CT, and significantly higher than those induced by recombinant CT-B.²² One of the mutants also induces Th2-type responses through a preferential inhibition of Th1-type CD4 T cells.

Fig. 19.8 Structure of CT/LT showing the pentameric B and the toxic A subunits. Mutants of both CT and LT have been produced through single amino acid substitutions in the A subunit. Generally, mutants of CT or LT lack residual enterotoxicity but retain mucosal adjuvant properties. (From McGhee JR, Kiyono H. The mucosal immune system. In: Paul WE, ed. Fundamental immunology. 1999, 909, with permission from Lippincott, Williams and Wilkins.)

Mutant LT molecules, whether possessing a residual ADP-ribosyltransferase activity (e.g., LT-A72R) or totally devoid of it (e.g., LT-RK and LT-S63K), can also function as mucosal adjuvants when administered intranasally to mice together with unrelated antigens.²³ As LT induces a mixed CD4 Th1- (i.e., IFN- γ) and Th2-type (i.e., IL-4, IL-5, IL-6 and IL-10) response,²¹ one might envisage the use of LT mutants when both Th1- and Th2-type responses are desired.

Safety of mucosal adjuvants and delivery systems

The olfactory neuroepithelium in the nasopharynx constitutes approximately 50% of the nasal surface and has direct neuronal connection to the olfactory bulbs (OBs) in the central nervous system (CNS). Although diarrhea is the primary limiting factor for the use of oral enterotoxin as an adjuvant in humans, major safety concerns with mucosal adjuvants and delivery systems for nasal vaccination are also important, as they may enter and/or target olfactory neurons and hence gain access to OBs and deeper structures in the brain parenchyma. These adverse effects appear to be mediated largely by ADP-ribosyl transferase activity and the nature of the cellular receptors targeted. Both native cholera toxin (nCT) and native labile toxin for humans (nLth-1) mutants bind to GM1 on epithelial cells and require endocytosis followed by transport across the epithelial cell to reach the basolateral membrane. GM1 gangliosides are also abundantly expressed by cells of the CNS, and their concentration on neuronal and microglial cells varies during the development of various cell types and different regions of the brain.²⁴

When given nasally to mice, nCT and CT-B enter the olfactory nerves and epithelium (ON/E) and OBs by mechanisms that are selectively dependent on GM1.²⁵ nCT as adjuvant also promotes the uptake of nasally co-administered, unrelated proteins into the ON/E. The targeting of CNS tissues by nasally administered bacterial enterotoxins is clearly related to a higher incidence of Bell's palsy (facial paresis) among volunteers of a nasal vaccination trial given nLTh-1 as mucosal adjuvant. Bell's palsy in study subjects who in 2000 received nonliving nasal influenza vaccine (Nasalflu®) led to its withdrawal from the market (www.niaid.nih.gov/dmid/enteric/intranasal.htm).

The use of GM1-receptor binding holotoxins as nasal mucosal adjuvants is currently inadvisable because of the risk of accumulation in the CNS. However, the development of nontoxic mCTs could overcome these potential problems.²⁶ To this end, a model adjuvant was developed by combining the ADP-ribosylating ability of nCT with a dimer of an Ig-binding fragment, D, of *Staphylococcus aureus* protein A.²⁷ This CTA1-DD molecule directly binds to B cells of all isotypes, but not to Mφ or DCs. Despite the lack of a mucosal binding element, the B cell-targeted CTA1-DD molecule was as strong an adjuvant as nCT. Notably, CTA1-DD promoted a balanced Th1/Th2 response with little effect on IgE Ab production. CTA1-DD did not induce inflammatory changes in the nasal mucosa, and most importantly did not bind to or accumulate in the OBs or the CNS.²⁸ CTA1-DD is an example of the use of nonganglioside targeting adjuvants and delivery systems as new tools for the development of safe and effective nasal vaccines.

Immunostimulatory DNA sequences

Plasmid DNA for gene vaccination can be functionally divided into two distinct units: a transcription unit and an adjuvant/mitogen unit.²⁹ The latter contains immunostimulatory sequences consisting of short palindromic nucleotides centered around a CpG dinucleotide core, as for example 5'-purine-purine-CG-pyrimidine-pyrimidine-3'. The adjuvant effect of these sequences is mediated by bacterial but not by eukaryotic DNA, owing to its high frequency of CpG motifs and to the absence of cytosine methylation. CpG motifs can induce B-cell proliferation and Ig synthesis as well as cytokine secretion (i.e., IL-6, IFN- α , IFN- β , IFN- γ , IL-12 and IL-18) by a variety of immune cells.

Because CpG motifs create a cytokine microenvironment favoring Th1-type responses, they can be used as adjuvants to stimulate antigen-specific Th1-type responses or to redirect harmful allergic or Th2-dominated autoimmune responses. Indeed, co-injection of bacterial DNA or CpG motifs with a DNA vaccine or with a protein antigen promotes Th1-type responses even in mice with a pre-existing Th2-type immunity. CpG motifs can enhance both systemic and mucosal immune responses when given intranasally to mice.³⁰

Mucosal cytokines and innate factors as adjuvants

Mucosal delivery of cytokines offers a means to prevent the adverse effects associated with the large and repeated parenteral doses often required for the effective targeting of tissues and organs. For example, nasal delivery permits the acquisition of significant serum levels of IL-12 at one-tenth the dose required for parenteral administration, complete with inhibition of serum IFN- γ .¹ A nasal vaccine of tetanus toxoid (TT), given with either IL-6 or IL-12, induced serum TT-specific IgG

Ab responses that protected mice against a lethal challenge with tetanus toxin.³¹ Also, nasal administration of TT with IL-12 as adjuvant induced high titers of S-IgA Ab responses in the GI tract, vaginal washes and saliva.³¹ Similar results were reported when mice were immunized nasally with soluble influenza H1 and N1 proteins and IL-12. In related studies, IL-12 given by the oral or intranasal routes was shown to redirect CT-induced antigen-specific Th2-type responses toward the Th1 type.¹ IL-12 was also shown to promote both Th1- and Th2-type responses when administered by a separate mucosal route.¹ These observations document the power of IL-12 for the induction of targeted immunity.

Innate molecules secreted in the epithelium provide another mechanism by which the adaptive mucosal immune system may be activated. To test this concept, protein antigens were given with either IL-1, α -defensins (i.e., HNP) or lymphotactin.¹ Lymphotactin, a C chemokine (Chapter 11) produced by NK and CD8 T cells such as TCR $\gamma\delta$ IELs, is chemotactic for T and NK cells and induces the migration of memory T cells across endothelial cells. IL-1 is produced by a number of cells, including macrophages and epithelial cells, whereas α -defensins are produced by Paneth cells. Nasal administration of protein antigens with these innate molecules enhanced systemic immune responses to co-administered antigens. However, whereas both IL-1 and lymphotactin produced mucosal S-IgA Ab responses, the defensins failed to do so.¹ Thus, some, but not all, inflammatory cytokines and molecules of the innate immune system can be effectively administered by mucosal routes to regulate both systemic and mucosal immune responses.

Flt3 ligand (FL) binds to the *fms*-like tyrosine kinase receptor Flt3/Flk2. FL mobilizes and stimulates myeloid and lymphoid progenitor cells, dendritic cells (DCs), and natural killer (NK) cells. Although FL dramatically augments numbers of DCs *in vivo*, it fails to induce their activation. Treatment of mice by systemic injection of FL can induce a marked increase in the numbers of DCs in both systemic (i.e., spleen) and mucosal lymphoid tissues (i.e., iLP, PPs and mesenteric lymph nodes [MLNs]). Other than leading to the increase in mucosal DCs can, in some cases, initially enhance the induction of oral tolerance;³² in many others it can favor the induction of an immune response by mucosal, systemic or cutaneous routes. In recent studies, plasmid encoding FL cDNA (pFL) has been co-administered with plasmids encoding protein Ags or linked to the Ag itself. These studies confirm the adjuvant activity of FL for both Ab and CMI responses and suggest that the costly treatment using FL protein may now be replaced by use of FL cDNA.³³

Transgenic plants

Plants can be engineered to synthesize and assemble one or more Ags that retain both T- and B-cell epitopes and can induce systemic and mucosal immune responses in both mice and humans.^{34,35} In order to circumvent potential denaturation of antigen during cooking, recombinant bananas have been developed that can accumulate up to 1 mg of vaccine Ag per 10 g of banana. Most recently, T-cell epitope peptides of allergens of Japanese cedar pollen have been expressed under the control of the rice seed storage protein glutelin (GluB-1) promoter. Oral feeding of GluB-1 to mice resulted in the induction of oral tolerance to pollen allergens.³⁶ Furthermore, transgenic rice expressing CT-B using GluB-1 promoter successfully induced CT-B-specific immunity when orally immunized.^{36a}

KEY CONCEPTS

SECRETORY IgA

- >> Unlike serum IgA, mucosal secretion of IgA reaches adult levels early in life (1 month to 2 years).
- >> The polymeric Ig receptor (pIgR) is expressed on the basolateral surface of epithelial cells and facilitates the active transport of secretory IgA, as well as pentameric IgM, into the mucosal secretions.
- >> Secretory IgA protects the host by inhibiting microbial adherence; neutralizing viruses, enzymes, and toxins; and engaging in anti-inflammatory activities by means of inhibiting IgM and IgG complement activation.
- >> Clinically, selective IgA deficiency, which is the most common primary immune deficiency, is characterized by recurrent mucosal infections, including sinusitis, otitis media, bronchitis, and pneumonias of viral or bacterial origin, as well as acute diarrhea caused by viruses, bacteria or parasites such as *Giardia lamblia*.

SYNTHESIS AND FUNCTIONS OF SECRETORY ANTIBODIES

In terms of both specific Ab activity and molecular size, mucosal S-IgA differs from bone marrow-derived serum IgA. In external secretions, adult levels of S-IgA are reached considerably earlier (1 month to 2 years) than in the serum (adolescence) (Chapters 32 and 34). Approximately 98% of S-IgA antibodies (Abs) are produced locally in mucosal tissues, with only a minor fraction deriving from the circulation.

Humans possess two α gene segments, $\alpha 1$ and $\alpha 2$ (Chapter 4), whose use defines the two IgA subclasses, IgA1 and IgA2.³⁷ (Fig. 19.7) These IgA subtypes differ primarily in their hinge regions. IgA1 Abs contain an additional set of 13 amino acid residues in the hinge region that renders them more flexible and susceptible to IgA1-specific proteases produced by bacteria. IgA1-secreting plasma cells are prevalent in most human mucosal tissues, especially the small intestine and the respiratory tract, whereas the human colon and genital tract are enriched for IgA2-secreting cells. Although S-IgA at mucosal surfaces has often been viewed as a barrier to prevent adhesion and colonization of pathogens, as well as an effective means to neutralize viruses and toxins, these antibodies confer the additional advantage of providing anti-inflammatory properties.⁸

POLYMERIC Ig RECEPTOR AND pIgA TRANSPORT

The polymeric Ig receptor (pIgR) is synthesized as a transmembrane protein by epithelial cells and is found on the basolateral surface of epithelial cells. It acts as a receptor for the endocytosis of polymeric IgA (pIgA) and pentameric IgM, both of which typically contain a J chain. pIgR is produced by bronchial epithelial cells, renal tubules, glands, and the epithelium of the small and large intestines.¹ pIgR is not expressed by the FAE (including M cells) of PPs, but only by the adjacent

columnar epithelial cells. It is expressed mainly in the upper respiratory tract (nasal cavity, tonsils, trachea, bronchi and tracheobronchial glands), expression in the lower tract being restricted to the pulmonary alveolar cells. In the female reproductive tissues the expression of pIgR is influenced by sex hormones and is low in the vagina, absent in the ovary and myometrium, and very high in the fallopian tubes and uterus. Normal kidneys do not express pIgR, whereas epithelial cells in the lower urinary tract may normally express pIgR and transport pIgA into urine. The expression of pIgR can be upregulated by cytokines such as IFN- γ , TNF- α , IL-1 α , IL-1 β and TGF- β .

IgA-MEDIATED INHIBITION OF MICROBIAL ADHERENCE

The inhibition of microbial adherence plays a critical initial role in the protection of the host and is mediated by both specific and nonspecific mechanisms. For example, S-IgA and pIgA are more effective at agglutinating microorganisms than is mIgA, and the agglutinating ability of S-IgA specific for capsular polysaccharides of *Haemophilus influenzae* appears to be crucial in order to prevent colonization by *H. influenzae*.³⁸ When a microorganism interacts with S-IgA molecules its surface becomes less hydrophobic and thus less likely to interact with the mucosal epithelium, but at the same time more likely to be entrapped in the mucus. Carbohydrate chains on the S-IgA molecule bind to bacteria and other antigens, and so represent another nonspecific mechanism that inhibits microbial adherence.

NEUTRALIZATION BY S-IgA OF VIRUSES, ENZYMES AND TOXINS

S-IgA Abs have been shown to be effective at neutralizing viruses in several experimental systems (e.g. influenza, Epstein-Barr virus, HIV, etc.) and at different steps in the infectious process. S-IgA specific to influenza hemagglutinin can interfere with the initial binding of influenza virus to target cells or with the internalization and the intracellular replication of the virus. Indeed, *in vitro* experiments using polarized murine epithelial cells have demonstrated that Abs specific to rotavirus and hepatitis virus can neutralize the viruses inside epithelial cells. Finally, S-IgA can neutralize the catalytic activity of many enzymes of microbial origin.

ANTI-INFLAMMATORY ACTIONS MEDIATED BY S-IgA Abs

IgA Abs are unable to activate complement by either the classic or the alternative pathway (Chapter 20). Nevertheless, they can interfere with IgM- and IgG-mediated complement activation.³⁷ S-IgA can inhibit phagocytosis, bactericidal activity and chemotaxis by neutrophils, monocytes and macrophages. IgA can downregulate the synthesis of TNF- α and IL-6, as well as enhancing the production of IL-1R antagonists by LPS-activated human monocytes. Thus, the antiflogistic properties of IgA are of significant importance for the integrity of the mucosa, in that IgA can limit bystander tissue damage that may result from the continuous interactions of the mucosa with myriad dietary and environmental antigens. Systemically, circulating IgA also appears to help limit inflammatory reactions that result from complement fixation and phagocyte activation, and contributes to the inhibition of IgE-dependent anaphylactic responses.

KEY CONCEPTS

MUCOSAL CYTOTOXIC T CELLS

- >> After enteric infection or immunization, antigen-stimulated CTLs are disseminated from Peyer's patches into mesenteric lymph nodes via the lymphatic drainage.
- >> Oral immunization with live virus can induce antigen-specific CTLs in both mucosal inductive and effector tissues for mucosal responses, as well as in systemic lymphoid tissues.

IgA DEFICIENCY

After AIDS, selective IgA deficiency (IgAD) is the most primary immune deficiency in individuals of European descent (Chapter 34). The clinical diagnosis of IgA deficiency depends on the relative absence of IgA in the serum. However, the most important manifestations of the disorder reflect primarily the absence of both S-IgA1 and S-IgA2 in the external secretions. Thus, IgA deficiency affects both the mucosal and systemic immune compartments, with only rare individuals exhibiting a superselective loss of either IgA1 or IgA2 alone.³⁹

Approximately one-third of individuals with IgAD suffer recurrent mucosal infections, including sinusitis, otitis media, bronchitis and pneumonias of viral or bacterial origin,³⁹ as well as acute diarrhea caused by viruses, bacteria or parasites such as *Giardia lamblia*. Other respiratory problems seen in IgA-deficient subjects include allergies, sinusitis, asthma and eczema. It has been suggested that loss of normally protective S-IgA Abs facilitates the development of IgE-type responses.

MUCOSAL CYTOTOXIC T LYMPHOCYTES

M cells have specific receptors for mucosal virus that allow certain viruses, such as the reovirus, to enter the cells in both NALT and GALT. It is likely that enteric viruses such as rotavirus, and respiratory pathogens such as influenza and respiratory syncytial virus (RSV), also enter the mucosal inductive pathway via M cells.⁴⁰ After enteric infection or immunization, antigen-stimulated CTLs are disseminated from PPs into MLNs via the lymphatic drainage. Oral immunization with live virus can thus induce antigen-specific CTLs in both mucosal and systemic lymphoid tissues.

ENTERIC VIRUSES AND MUCOSAL CTLs

CD8 CTLs (Chapter 18) play a central role in rotavirus and reovirus immunity.^{41,42} Reovirus-induced CTL precursors (pCTLs) in GALT migrate to the systemic compartment. Reovirus-specific CD8 CTLs associated with the $\alpha\beta$ T-cell population are also observed in the IELs. Oral delivery of rotavirus increases pCTLs in GALT and results in their dissemination throughout the murine lymphoid system within 3 weeks. Moreover, adoptively transferred CD8 T cells mediate the clearance of rotavirus infection in SCID mice.

RESPIRATORY VIRUSES AND MUCOSAL CTLs

Studies of immune responses after intranasal infection with influenza virus in CD4 knockouts or other mice in which this subset had been depleted have shown that CD4 T cells do not affect the induction of pCTLs or significantly alter the clearance of infection.⁴³ Clearance of influenza is unaltered by the use of β_2 -microglobulin knockout mice, which lack CD8 T cells, or of mice that have been treated with monoclonal anti-CD8. $\gamma\delta$ T cells with several V δ chain specificities increase in the infected site as clearance occurs, which suggests a regulatory role for $\gamma\delta$ T cells in antiviral immunity.⁴⁴

Effector CTLs protect mice from respiratory syncytial virus (RSV) infection. The RSV F determinant, a 22 kDa glycoprotein, is a major target of pCTLs and CTL induction by RSV or recombinant vaccinia virus-expressing F glycoprotein-induced protective CTLs. IFN- γ -producing CD4 Th1 cells, as well as CD8 T cells, are associated with recovery, whereas CD4 Th2-type pathways are not.⁴⁵

MUCOSAL AIDS MODELS FOR CTL RESPONSES

Approximately 80% of new HIV-1 infections result from sexual transmission (Chapter 38). Thus, significant efforts have been focused on the development of mucosal immunity in the genital tract. Studies using the Rhesus macaque and the simian immunodeficiency virus (SIV) vaginal infection model have provided direct evidence that pCTLs occur in female macaque reproductive tissues, and that infection with SIV induces CTL responses. This important finding was recently extended to vaginal infection with an SIV/HIV-1 chimeric virus (SHIV) containing HIV-1 89.6 *env* gene.⁴⁶ Recent work has shown that intranasal immunization with SIV/HIV components induces Ab responses in vaginal secretions. Intranasal immunization of mice with HIV-1 T-cell epitopes and the mucosal adjuvant CT has been shown to induce functional CTLs.

OTHER MUCOSAL CTL SYSTEMS

Salmonella can elicit CD8 T-cell responses, including CTLs, to expressed proteins, and CD8 T cells induced to the parasite *Toxoplasma gondii* have been shown to be protective. Thus, mucosal CD8 CTLs can also be induced in nonviral situations. Significant questions remain about the mechanism by which naïve CD8 T cells can be triggered to expand into pCTLs, and the rules for expression of effector CTLs and memory in the actual mucosal compartment that manifests the infection. It has been shown that pCTLs accumulate in immunologically privileged sites but do not develop a cytotoxic function until they encounter infected class I MHC-presenting target cells. It is possible that this mechanism protects the common mucosal immune system network from inadvertent cytotoxic inflammatory events.

CELLS IN THE EPITHELIUM FORM A REGULATORY INTRANET

A major hallmark of the mucosal immune system is the presence of a mucosal intranet consisting of epithelial cells, TCR $\alpha\beta$ Th1 and Th2 T cells, TCR $\gamma\delta$ T cells, and IgA-committed B cells for the induction and regulation of Ag-specific S-IgA Abs in external secretions. Epithelial

cells not only provide a physical barrier, but also produce and express a variety of glycoproteins, peptides, cytokines and receptors that are important components of mucosal immunity. In addition, this epithelial layer contains a large number of CD3 T cells commonly termed intraepithelial lymphocytes (IELs). Both intestinal epithelial cells (IECs) and IELs are considered key players in the mucosal intranet. Lymphoepithelial interactions contribute both to the maintenance of mucosal immunity and to homeostasis against infection.

ORIGIN AND FUNCTION OF INTESTINAL INTRAEPITHELIAL LYMPHOCYTES

IELs reside on the basolateral surface of epithelial cells that cover the GI, nasal and reproductive tracts. The most striking characteristic of mouse IELs is the presence of high numbers of $\gamma\delta$ T cells; however, most human IELs express oligoclonal $\alpha\beta$ TCR.⁴⁷ Human IELs appear to originate from cells in the lamina propria, but also have the potential to migrate back to this region. Crypt patches that can be identified in crypt regions of the intestinal lamina propria of mice contain *c-kit*⁺ cells that are negative for lineage markers (CD3, B220, Mac-1, Gr-1 and TER119) and which can differentiate into both $\alpha\beta$ and $\gamma\delta$ IELs.

IELs may be assumed to be a primary source of effector T cells in the natural environment of the mucosal epithelium. Thus, CD8 IELs possess cytotoxic activity and kill a tumor epithelial cell line by mechanisms that are different from those of natural killer (NK) cells.⁴⁷ Cytotoxic activity in CD8 IELs is restricted to epithelial cells, suggesting that CD8 IELs in humans have an immune surveillance function focused on identifying and removing defective or infected intestinal epithelial cells. $\gamma\delta$ T cells appear to be required for the control of mycobacterial infection and contribute to immunity following *Plasmodium yoelii* vaccination, as TCR $\delta^{-/-}$ mice do not respond to these intracellular microorganisms and die of infection.⁴⁸ $\gamma\delta$ T cells may also regulate mucosal IgA responses, as TCR $\delta^{-/-}$ mice display markedly decreased IgA responses after oral immunization.

INTESTINAL EPITHELIAL CELL FUNCTIONS IN HOST DEFENSE

Epithelial cells can secrete regulatory cytokines. For example, freshly isolated colonic epithelial cells express mRNA for IL-6 and IL-8,⁴⁸ and intestinal and urinary tract epithelial cell lines can secrete IL-6 after stimulation with *Escherichia coli*. Invasive strains of bacteria, such as *Salmonella dublin*, *Shigella dysenteriae*, *Yersinia enterocolitica*, *Listeria monocytogenes* and enteroinvasive *E. coli*, can also induce colonic epithelial cell lines to produce a characteristic array of proinflammatory cytokines shortly after infection/stimulation. These include IL-8, monocyte chemotactic protein-1 (MCP-1), granulocyte-macrophage colony-stimulating factor (GM-CSF) and TNF- α . Respiratory syncytial virus (RSV) can induce upper airway epithelial cells to produce the chemokine RANTES, and human intestinal epithelial cell lines can express mRNA for IL-1 α , IL-1 β , IL-10 and TNF- α .

Intestinal epithelial cell lines can also express adhesion molecules necessary for APCs to interact with lymphocytes. Both intercellular adhesion molecule-1 (ICAM-1) and lymphocyte function-associated antigen-3 (LFA-3) can be expressed by human intestinal epithelial cell lines, and the expression of ICAM-1 can be enhanced by exposure to the inflammatory cytokines such as IFN- γ , TNF- α , IL-1 β and IL-6.⁴⁸

Finally, both gastric epithelial cell lines, as well as freshly isolated epithelial cells, can express both B7-1 (CD80) and B7-2 (CD86).

INTRAEPITHELIAL LYMPHOCYTES AND EPITHELIAL CELL CROSS-TALK AT THE MUCOSAL BARRIER

It is logical to consider that epithelial cells and IEL T cells in mucosal tissues cross-regulate each other to induce and maintain appropriate immunological homeostasis. IEL T cells produce an array of cytokines, including TGF- β and IFN- γ , which induce high levels of MHC expression on epithelial cells.⁴⁸ Further, IEL T-cell-derived cytokines, including IFN- γ , IL-4 and TNF- α , influence epithelial cell functions, such as the production of the pIgR.¹ Intraepithelial $\gamma\delta$, but not $\alpha\beta$, T cells regulate the growth and differentiation of epithelial cells.⁴⁸ Regulation is bidirectional, as epithelial cells can also influence $\gamma\delta$ T-cell development and function. Both human and murine intestinal epithelial cells contain specific mRNA for IL-7,⁴⁸ a cytokine that stimulates $\gamma\delta$ T-cell proliferation *in vitro*. Epithelial cells also produce stem cell factor (SCF), which appears important for the development and maintenance of intestinal intraepithelial $\gamma\delta$ T cells. Intraepithelial $\alpha\beta$ T cells respond to IL-7 and SCF produced by intestinal epithelial cells, and thus actively contribute to the mucosal intranet.

MUCOSALLY INDUCED TOLERANCE

The suppression of systemic immune responses by oral feeding of antigen has been termed oral tolerance.⁴⁹ The finding that nasal delivery of Ag also induces this effect has led to the term mucosally induced tolerance. Oral tolerance involves at least three possible mechanisms, whose contributions depend on the dose and frequency of administration.⁵⁰ High oral doses favor clonal anergy, a state of T-lymphocyte unresponsiveness to the antigen that is characterized by absence of proliferation, IL-2 secretion and IL-2R expression (Chapter 13). In contrast, low doses favor tolerance by active suppression. The mechanism regulating high-dose tolerance appears distinct from that for low-dose tolerance. Regulatory type 1 T (Tr1) cells were first shown to play a central role in suppressing the development of inflammatory bowel disease. This type of Treg cell differentiates from naïve T cells and regulates oral tolerance to food Ags, bacterial flora and pathogens.⁵¹ Thus, one should call them acquired-type Treg cells. It has been shown that acquired-type Treg cells perform their immunoregulatory function mainly by producing inhibitory cytokines such as IL-10 and TGF- β 1. Another type of naturally occurring regulatory CD4 T cell has also been described for maintenance of host homeostasis. This type of CD4 T cell was designated an innate-type Treg cell and was shown to express cell-surface CD25 and intracellular *Foxp3* molecules (Chapter 16). Innate-type Treg cells play a role in controlling the proliferation, expansion and differentiation of naïve T cells in a direct cell contact fashion, and migrate preferentially into lymphoid tissues, mainly the spleen.⁵¹ Thus, innate-type Treg cells most likely express CTLA-4 (CD152) and GITR on their cell surface.

ORAL TOLERANCE

Increasing attention is being paid to oral tolerance and the role it might play in the prevention or treatment of autoimmune diseases, including multiple sclerosis, rheumatoid arthritis, uveitis, type 1 diabetes mellitus

CLINICAL RELEVANCE

MUCOSALLY INDUCED TOLERANCE

- >> Oral feeding or nasal delivery of antigen can result in the suppression of systemic immune responses.
- >> High oral doses favor clonal anergy.
- >> Low oral doses favor tolerance by active suppression.

and contact hypersensitivity.⁵⁰ The first study in humans showed that oral tolerance could be induced to the model neoantigen keyhole limpet hemocyanin (KLH). The induced unresponsiveness consisted of systemic T-cell tolerance; however, B-cell responses were primed in both systemic and mucosal sites. Antigen-specific T cells secreting large amounts of TGF- β have been observed in the blood of multiple sclerosis patients treated orally with a bovine myelin preparation. It has been suggested that these cells represent a distinct T-cell lineage of presumed mucosal origin, designated Th3 cells, that suppresses inflammation in the local environment and thus contributes to oral tolerization. Subsequently, oral desensitization to nickel allergy was reported to reduce nickel-specific T cells and the cutaneous form of eczema. Despite these encouraging results, no differences were observed between the placebo- and the orally treated group in large-scale trials where single-dose bovine myelin was administered to relapsing–remitting multiple sclerosis patients, or where bovine type II collagen was administered to rheumatoid arthritis patients. Taken together, these initial trials have shown that oral tolerance paralleling the results in animal models could be induced in humans. However, a consistent clinical efficacy remains to be shown.

NASALLY INDUCED TOLERANCE

The initial dogma that mucosally induced tolerance requires intestinal processing of the antigen was recently challenged by the observation that systemic unresponsiveness could be achieved by administration of the antigen via the nasal or aerosol route. These routes were found to require lower doses of antigens than did oral administration, a discrepancy that can be explained by the dilution effect as well as the potential degradation of the antigen in the GI tract. The precise mechanisms behind nasally induced tolerance are not yet known.

MUCOSAL IMMUNE RESPONSES IN AGING

Immune functions are known to deteriorate with age in several species. The risk and severity of infections are greater, and the susceptibility to certain types of autoimmune diseases and cancer are greater in the elderly,⁵² whereas responses to vaccination are diminished. These studies provide evidence of dysregulation and of an overall decline in host immunity with increasing age. In systemic immune compartments, the age-associated alterations have been studied extensively. Dysfunctions occur in both B and T cells, though the latter are considered to be more susceptible to immunosenescence.

The most common method of evaluating mucosal immune responses is perhaps to test external secretions for the presence of S-IgA Abs. Total IgA Ab levels in mucosal secretions either increase or remained unchanged with age, and fecal extracts from 1-year old mice appear to contain similar IgA levels.⁵³ B cells from PPs of aged mice stimulated with autoreactive T-cell hybridoma-derived B-cell stimulatory factors produce significantly higher levels of IgA Abs than do those from young adult mice.

In humans, it has been shown that elderly subjects have significantly higher concentrations of salivary S-IgA Abs than younger subjects, whereas whole gut lavages of aged and young subjects contain similar amounts of Abs.⁵³ Analogous results have also been obtained for total IgA Ab responses in serum of aged animals and humans. These results indicate an absence of age-associated impairment in total IgA Ab levels in external secretions.

Antigen-specific IgA B-cell responses play a central role in the induction of mucosal immunity to infectious diseases.¹ The GI tract in the elderly is particularly susceptible to infectious diseases, suggesting that mucosal immunity is also affected in aging.⁵³ In fact, in elderly humans pathogens that invade through mucosal surfaces, such as the influenza virus and the bacterial pathogen *Streptococcus pneumoniae*, cause more severe and more frequently lethal infections. Antigen-specific immune responses in aged animals and humans have also been investigated. Intestinal lavage from aged rats given oral nCT contain significantly lower titers of anti-CT-B IgA Abs than those from identically immunized young rats. Furthermore, the numbers of IgA AFCs in the intestinal lamina propria were also reduced in aged rats and rhesus macaques given oral nCT. When aged mice are orally immunized with HA from influenza along with nCT as mucosal adjuvant, HA-specific S-IgA Ab responses are also lower than in young mice. These results indicate that Ag-specific mucosal IgA Ab responses are diminished in aged animals, especially those in the GALT.⁵³

When challenged with three nasal administrations of OVA (100 μ g) plus nCT (0.5 μ g) as mucosal adjuvant at weekly intervals, significant OVA-specific S-IgA Ab responses occurred in the external secretions of both young adult and 1-year old mice.⁵³ Significant and comparable OVA-specific IgG and IgA Ab responses were also seen in the plasma. However, nasal immunization failed to induce mucosal immune responses in aged (2-year old) mice despite the presence of an intact NALT-induced systemic immune response.

Complement and complement deficiencies

Terry W. Du Clos, Carolyn Mold

20

The complement system is an important part of the innate immune system and a major effector mechanism of humoral immunity.^{1, 2} It is comprised of a group of serum proteins that are activated through sequential protease-based steps similar to the coagulation, fibrinolytic, and contact pathways. The complement activation pathways include potent amplification steps as well as critically important fluid-phase and cell membrane regulatory proteins. Complement activation is linked to cellular responses by the recognition of cleaved complement proteins by receptors on leukocytes and vascular cells. The components of the complement system, including complement regulatory proteins and receptors, are shown in Table 20.1. The three primary roles of complement in host defense against infection are: (1) to activate an inflammatory response; (2) to opsonize microbial pathogens for phagocytosis and killing; and (3) to lyse susceptible organisms. The complement system also provides a bridge between the innate and adaptive immune responses through receptors on B lymphocytes and antigen-presenting cells (APC). Three pathways have been described that share these functions. These pathways differ in their initiation steps and thus are activated in response to different threats. Activation of the complement cascade is amplified at several key steps so that it has the potential to induce a rapid, massive inflammatory response. Complement activation is normally targeted and highly regulated to focus this response. However, complement activation also contributes to tissue injury in infectious, autoimmune, and inflammatory diseases where it may amplify the response to immune complex deposition or tissue damage.

COMPLEMENT PATHWAYS

Three pathways of complement activation have been described: the classical, alternative, and lectin pathways (Fig. 20.1). The classical pathway is the complement pathway that is initiated by immunoglobulin M (IgM) and IgG antibody binding to antigen. It participates with natural IgM in early host defense,³ and provides a mechanism for immune complex and apoptotic cell clearance.¹ The classical pathway may also be activated by innate pattern recognition molecules such as the pentraxins, C-reactive protein (CRP) and serum amyloid P (SAP) component,^{4, 5}

KEY CONCEPTS

COMPLEMENT PATHWAY ACTIVATORS

Classical pathway

- >> IgM-containing immune complexes
- >> IgG-containing immune complexes
- >> C-reactive protein and serum amyloid P–ligand complexes
- >> Phospholipids on ischemic and apoptotic cells
- >> C4 nephritic factor (C4NeF)
- >> Myelin

Alternative pathway

- >> Bacterial cell wall components: lipopolysaccharide, teichoic acids
- >> Amplification from classical pathway C3b
- >> Fungal cell wall polysaccharides: zymosan
- >> Virus-infected cells (measles, influenza, Epstein–Barr virus)
- >> Immunoglobulin A (IgA)-containing immune complexes
- >> C3 nephritic factor (C3NeF)
- >> Cobra venom factor
- >> Some tumor cell lines
- >> Deoxygenated sickle cells

Lectin pathway

- >> Repeating simple sugars
- >> IgA bound to antigen
- >> IgM bound to antigen
- >> Apoptotic cells

Table 20.1 Proteins of the complement system

Component	Concentration (μg/ml)	Molecular weight
Classical pathway		
C1q	66	410 000
C1r	48	170 000
C1s	34	85 000
C4	400	206 000
C2	30	117 000
Lectin pathway		
MBL	2 (wide range)	600 000
MASP-1	5	83 000
MASP-2	5	52 000
Alternative pathway		
C3	1200	195 000
Factor B	200	95 000
Factor D	3	24 000

C5aR (CD88)		50 000
C3aR		60 000

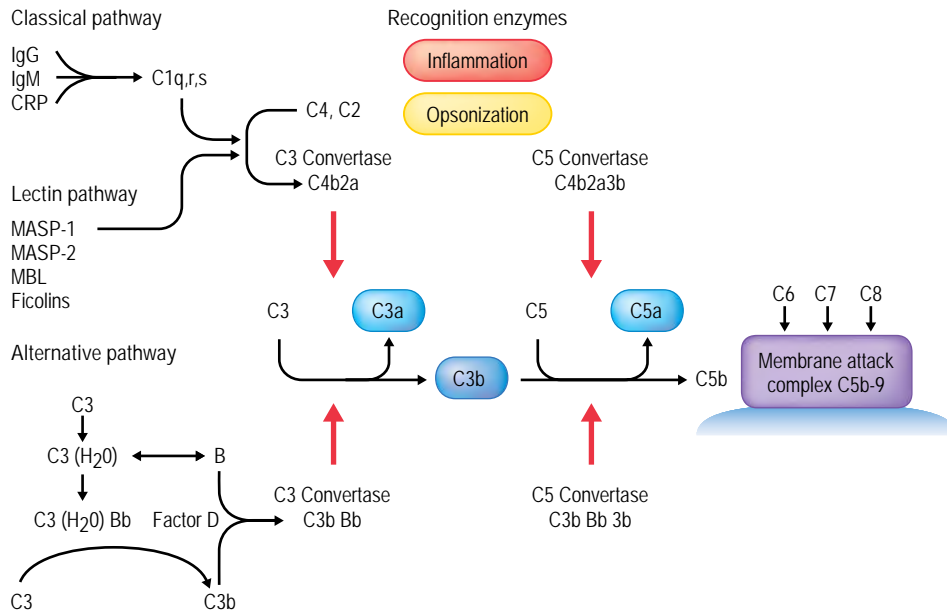

Fig. 20.1 Overview of the complement pathways indicating components required for recognition, enzymatically active components and complexes, major opsonic, inflammatory and membranolytic products.

and the membrane-bound lectin, SIGN-R1.⁶ The lectin pathway uses most of the classical pathway components, but is activated by mannose (or mannan)-binding lectin (MBL) and the ficolins, which are lectins that recognize repeating carbohydrate patterns on microorganisms.⁷ The alternative pathway is believed to be the most ancient pathway in an evolutionary sense, and also has the broadest recognition ability.⁸ The alternative pathway is activated by surface components of all types of microorganisms, including bacteria, fungi, parasites, viruses, and virus-infected cells. The alternative pathway differs from the classical and lectin pathways in its ability to autoactivate when tightly regulated inhibitory signals are absent.⁹ This mechanism promotes its function as an innate and rapid response to infection. The alternative pathway also provides an important amplification mechanism for classical or lectin pathway activation, resulting in greater opsonization and generation of the terminal pathway.¹⁰

CLASSICAL PATHWAY

The classical pathway is usually focused by antibody binding to a target antigen. In general, the ability of antibodies to activate complement is: IgM > IgG₃ > IgG₁ > IgG₂ >> IgG₄. Binding of these antibodies exposes sites in the Fc region for attachment of the first subcomponent of complement, C1q. C1 is a large calcium-dependent complex composed of C1q, and two molecules each of the proenzymes, C1r and C1s. C1q is a 410-kDa protein with six globular heads connected by a collagen-like tail. For IgM, which is pentameric, binding to antigen creates a conformational change that exposes the C1q binding site in the Cμ3 domain. For IgG, at least two closely bound molecules are required to provide multiple attachment points for C1q binding to the Cγ2 domain. Similarly, CRP or SAP molecules bound to ligand provide multiple C1q

binding sites resulting in classical pathway activation. IgM, IgG, and CRP bind C1q through its globular head groups.¹¹ Membrane lipids exposed on apoptotic cells or mitochondrial membranes, polyanions, nucleic acids, and endotoxins activate the classical pathway differently through charge-based interactions with the collagen-like region of C1q.¹²

Once C1q binds to an activator through several globular heads, C1r is cleaved and activated by an autocatalytic process.¹¹ Activated C1r then cleaves and activates C1s, which cleaves circulating C4. C4 and C3 are highly homologous proteins that share an unusual internal thioester bond¹³ (Fig. 20.2). Cleavage of C4 releases the C4a fragment, and exposes the reactive thioester bond in the larger C4b fragment. This allows C4b to attach covalently to nearby target structures, through either amide or ester bonds, to amino or carboxyl groups on proteins, glycoproteins, or polysaccharides on cell surfaces, antibodies, and antigens. The exposed thioester bond is reactive, but unstable, and only about 5% of the C4 typically becomes attached to the target prior to inactivation of the thioester site by hydrolysis. Bound C4b provides an anchor site for C2 attachment, which is then cleaved by C1s, releasing C2b.

The complex of C4b2a is termed the classical pathway C3 convertase, because it has the capacity to cleave C3, releasing C3a. The C2a component of the complex contains the active enzymatic site. C3 cleavage is similar to C4 cleavage in that the larger fragment, C3b, contains a thioester site (Fig. 20.2) that can mediate covalent attachment to nearby surface structures, including the antigen, antibody, and the attached C4b. C3 is found at higher concentration in serum than C4, and its cleavage is amplified by the alternative pathway. Thus, efficient complement activation will result in a cluster of multiple bound C3b molecules that can be recognized by cellular receptors. C3b that attaches to C4b within the C3 convertase produces the trimolecular complex C4b2a3b, which is a

Fig. 20.2 Exposure and reactivity of the C3 thioester bond. C3 cleavage by a C3 convertase generates metastable C3b with a reactive thioester. Metastable C3b may be hydrolyzed to form C3b(H₂O) or may react with hydroxyl or amino groups to become covalently bound to a surface.

C5 convertase. Cleavage of C5 produces C5a, which has potent inflammatory activity and C5b, which initiates the formation of the membrane attack complex (MAC) (Fig. 20.3).

LECTIN PATHWAY

The lectin pathway is similar to the classical pathway, except that it uses pattern recognition molecules, MBL, M-ficolin and H-ficolin, instead of antibody to target activation.⁷ MBL is structurally similar to C1q, except that its globular-binding domains are C-type lectin domains specific for repeating carbohydrate structures found on microorganisms. Like C1q, MBL and ficolin are found in complex with serine proteases, MASPs (MBL-associated serum protease), which are structurally and functionally similar to C1r and C1s. There are four MASPs, MASP-1, 2, 3, and MASP-19, a truncated form of MASP-2, associated with MBL and the ficolins. However, the MBL-MASP-2 complex alone is sufficient to initiate the lectin pathway after ligand binding. MBL binding to mannan results in MASP activation and MASP-2 cleaves C4 and C2 to produce the same C3 convertase (C4b2a) as in the classical pathway. Direct C3 activation by MBL through MASP-1, bypassing C4 and C2, has also been reported. No natural substrate of MASP-3 has been identified. Subsequent steps in the lectin pathway are identical to the classical pathway.

ALTERNATIVE PATHWAY

The alternative pathway uses proteins that are structurally and functionally homologous to those of the classical pathway in a different type of activation mechanism that does not require recognition of a target by specific antibody. Conceptually the alternative pathway can be thought of as continuously activated at a low level. This low level of activation is regulated on host cells and tissues by complement regulatory proteins.

Fig. 20.3 Sequence of protein interactions in the assembly of the membrane attack complex (MAC). C5b, generated by C5 convertase cleavage of C5, combines with C6 and C7 to form a hydrophobic complex capable of membrane interaction. Binding of C8 allows the complex to insert further into the membrane and forms a site for C9 polymerization. C9 polymers form the transmembrane pore-associated complement-mediated lysis of membranes.

Thus, it is the lack of regulation that targets alternative-pathway activation to microbial targets. The basis for the spontaneous activation of the alternative pathway, also referred to as 'tickover,' is the slow hydrolysis of the C3 thioester bond.⁹ Hydrolyzed C3, C3 (H₂O), assumes a conformation similar to that of C3b. C3 (H₂O) cannot attach to a target, but can bind factor B (homologous to C2), which is cleaved by factor D (homologous to C1s) to form a fluid-phase C3 convertase. This convertase cleaves C3 to generate C3b, which can covalently bind to nearby structures and form a bound C3 convertase (C3bBb). Because C3b is both a part of this enzyme and a product of the reaction, a positive-feedback loop is formed that rapidly deposits more C3b. Similar to the classical pathway, a C5 convertase is formed when C3b attaches to the C3 convertase.

Complement regulatory proteins found in the plasma and on cell membranes limit inappropriate alternative-pathway activation. The plasma protein, factor H¹⁴, is particularly important in controlling alternative-pathway activation both in the fluid phase and on 'nonactivating' surfaces, which recruit factor H through its binding sites for sialic acid and polyanions. 'Activating' surfaces, such as cell wall polysaccharides from fungi and gram-positive bacteria, endotoxins, some viral glycoproteins, IgA-containing immune complexes, and some tumor cell lines share the ability to provide C3b attachment sites that are protected from regulatory proteins. The alternative-pathway C3 and C5 convertases are both stabilized by properdin (factor P), for which this pathway was originally named. An important role of the alternative pathway is the amplification of C3b deposition and C5 convertase generation that is initiated by the classical or lectin pathways.¹⁰

MEMBRANE ATTACK COMPLEX

All three complement pathways merge with the cleavage of C5 into C5a and C5b. Although C5 is structurally homologous to C3 and C4, it lacks the internal thioester bond that allows covalent attachment of C3b and C4b to surfaces. C3a, C4a, and C5a are also structurally homologous and as described below are the most potent proinflammatory mediators of the complement system. C5b initiates the formation of the MAC (Fig. 20.3),

a complex of C5b, C6, C7, C8 and multiple C9 molecules.^{15,16} This complex, as indicated by its name, penetrates membrane bilayers to form pores that disrupt the osmotic barrier, leading to swelling and lysis of susceptible cells. Lysis of antibody-sensitized erythrocytes by the MAC is the basis of the hemolytic complement assay or CH₅₀. C5b initiates the formation of the MAC without further proteolytic steps. C5b binds to C6, and this complex binds to C7. The C5b67 complex is lipophilic and associates with cell membranes, if available, or with serum lipoproteins. Once bound to a membrane, C5b67 recruits C8 and the complex penetrates more deeply into the membrane. However, complete lysis requires C9, a pore-forming molecule with homology to perforin, a protein used by cytotoxic T cells and natural killer cells for killing virus-infected targets.¹⁷ The complex of C5b678 forms a nidus for C9 binding and polymerization.

■ REGULATION OF COMPLEMENT ACTIVATION ■

The complement cascade is rapidly activated and highly amplified by the generation of C3 and C5 convertases. There are three main levels of control that serve to limit the potential harm that uncontrolled complement activation might cause. These three levels are: (1) the initiation step in the classical pathway; (2) the C3 and C5 convertases of all three pathways; and (3) the assembly of the MAC. Both soluble and membrane-bound regulatory proteins serve these functions, which help terminate complement activation as well as direct it to appropriate targets.¹⁸

C1 ESTERASE INHIBITOR

C1 esterase inhibitor (C1-INH) is a serum glycoprotein and a serine proteinase inhibitor (serpin). C1-INH covalently binds to activated C1r and C1s, irreversibly inhibiting their activity and thereby limiting classical pathway activation. C1-INH inactivation of C1r and C1s also removes them from the C1 complex, exposing sites on the collagen-like region of C1q. C1-INH also inhibits MASP-1 and 2, kallikrein, factor XIa, XIIa and plasmin of the lectin pathway and the contact, coagulation, and fibrinolytic systems. As discussed later, inherited deficiency of C1-INH is the basis of hereditary angioedema, a disease characterized by recurrent attacks of subcutaneous or submucosal edema.

MATRIX PROTEOGLYCANS, DECORIN, AND BIGLYCAN

Decorin and biglycan are abundant extracellular matrix proteins in the small leucine repeat proteoglycan family. These proteins bind to collagens, and also to the collagen-like regions of C1q and MBL. Decorin and biglycan inhibit classical pathway activation, and biglycan also inhibits lectin pathway activation.¹⁹ Decorin also inhibits C1q interaction with receptors on endothelial cells and monocytes.

REGULATORS OF THE C3 AND C5 CONVERTASES

The C3 and C5 convertases are central to the generation of the inflammatory and opsonic products of complement activation and are highly regulated by fluid-phase and membrane-bound regulatory proteins. The convertases themselves are complexes of two or three components and one mechanism of regulation is the dissociation of these complexes. This type of regulation is termed 'decay acceleration.' A second mechanism of regulation is the enzymatic inactivation of the C4b and C3b components of the convertases (Fig. 20.4). This is accomplished by the plasma enzyme factor I, which is, however, only active on C4b or C3b complexed with one of several regulatory proteins. This type of regulation is termed 'cofactor activity.'

Factor I

Factor I (C3b inactivator, C3bINA) cleaves C4b and C3b into products that are recognized by specific cellular receptors, as discussed below. The sequential cleavage of C3b by factor I to iC3b and C3dg is depicted in Figure 20.4. C4b is cleaved in an analogous manner to C4d. (The iC4b intermediate is found only transiently.) The regulatory proteins that facilitate this cleavage by cofactor activity and those that inactivate C3 and C5 convertases by decay-accelerating activity are not enzymes, but are members of a family of structurally related proteins that are encoded within a genetic locus termed the regulators of complement activation (RCA) locus.²⁰ This family is characterized by a repeating subunit structure composed of complement control protein repeats (CCP), also known as short consensus repeats (SCR) or sushi domains. These units consist of 60–70 amino acids with a conserved disulfide bonding pattern and contain the recognition sites for C3b, C4b, and other ligands.

Soluble regulatory proteins, C4b-binding protein and factor H

C4b-binding protein (C4bp) and factor H are fluid-phase regulatory proteins with both decay-accelerating and cofactor activities. C4bp is multimeric, being composed of seven identical subunits, each containing eight CCPs. H is a single-chain protein composed entirely of 20 CCPs. C4bp is specific for C4b and the classical pathway convertases (C4b2a, C4b2a3b), whereas factor H regulates C3b and C3b-containing convertases (C3bBb, C3bBb3b, C4b2a3b). Factor H is essential for regulation of C3 'tickover,' and factor H deficiency results in acquired deficiency of C3. Additional binding sites on factor H that recognize sialic acid, poly-anions, CRP, and endothelial cells provide targeted regulation of alternative-pathway activation on surfaces.^{21,22}

Fig. 20.4 Factor I-dependent cleavage of C3 showing the structures of the products and the required cofactors.

Membrane regulatory proteins, CD55 (DAF), CD46 (MCP), CD35 (CR1), CRIT, and CSMD1

The RCA family also includes the membrane regulatory proteins decay-accelerating factor (CD55, DAF), membrane cofactor protein (CD46, MCP), and complement receptors CR1 (CD35) and CR2 (CD21). CD55 (DAF) and CD46 (MCP), as their names imply, have decay-accelerating and cofactor activities that prevent complement activation on cell membranes. Each has an extracellular domain composed exclusively of four CCPs. CD55, a glycosylphosphatidylinositol (GPI)-anchored protein, and CD46, a transmembrane protein, are widely distributed on cells in contact with the blood, with the exception that erythrocytes lack CD46. Soluble CD55 is also found in most biological fluids. Both protect cells from complement-mediated lysis. CD35 (CR1) has decay-accelerating and cofactor activity as well as receptor activity for immune complexes with bound C3b. The complement receptors are discussed later in the chapter.

Two new membrane regulatory proteins have recently been described that block the classical pathway C3 convertase. The first, named complement C2 receptor inhibitor trispanning (CRIT), was originally identified on *Schistosoma* and *Trypanosoma* parasites and later found to be widely expressed on human tissues and blood cells, except for neutrophils and erythrocytes.²³ CRIT competes with C4b for C2 binding, preventing its cleavage by C1s and blocking the formation of the classical pathway C3 convertase.

The second protein, CUB and sushi multiple domains 1 protein (CSMD1), was identified by the presence of 15 CCPs homologous to those of the RCA proteins. A recombinant form of the rat homologue of human CSMD1 blocks classical-pathway, but not alternative-pathway, activation and is expressed as a membrane protein in the central nervous system, particularly during development.²⁴

Properdin

In contrast to the regulatory proteins discussed above, properdin (factor P) stabilizes C3 and C5 convertases of the alternative pathway, increasing their activity.¹⁸ Properdin is found as noncovalently linked dimers, trimers, tetramers, and larger species composed of identical 56-kDa chains.

The majority of the protein consists of a series of six thrombospondin type 1 modules. Properdin binds to C3b and to Bb, preventing the spontaneous or induced decay of the alternative-pathway C3 and C5 convertases. Its multimeric structure promotes interaction with clustered C3b. The relative affinity of properdin binding is highest for C3bBb > C3bB > C3b.

REGULATORS OF THE MAC

The MAC is also regulated by both fluid-phase and membrane regulatory proteins.

Soluble MAC inhibitors, S protein, and clusterin

Soluble hydrophobic proteins can block the incorporation of MAC into membranes. Two well-characterized proteins with this activity are S protein (vitronectin), and clusterin (SP-40,40, apolipoproteins J). S protein²⁵ is found in the serum and extracellular matrix and binds to C5b-7. C8 and C9 can still bind to the complex, but membrane insertion and C9 polymerization are prevented. Soluble complexes of S protein and C5b-9 are found in the serum during complement activation and an SC5b-9-specific enzyme-linked immunosorbent assay (ELISA) has been used to monitor activation of the MAC. Clusterin²⁶ is found in the serum, in the male reproductive tract, and on endothelial cells of normal arteries. It is also associated with amyloid deposits, including β amyloid in Alzheimer's disease. Clusterin forms an inactive complex with C5b-9, preventing membrane insertion.

Membrane MAC inhibitor, CD59

The primary membrane-bound inhibitor of MAC is CD59 (MIRL, MACIF, HRF20, P18, protectin).²⁷ CD59 is a GPI-anchored protein found on most cells, and may also be found in a soluble form in biological fluids. CD59 binds to C8 in the C5b-8 complex, preventing the incorporation of C9. CD59 also blocks polymerization of C9 already in the MAC.

COMPLEMENT RECEPTORS

Many of the biological effects of complement activation are mediated by cellular receptors for fragments of complement proteins. These include receptors for the small soluble complement fragments, C5a and C3a, and receptors for bound complement fragments, C1q and cleaved forms of C4b and C3b. Receptors for bound C3 are specific for not only C3b, but further breakdown products generated by the enzymatic processing by factor I in conjunction with the cofactor proteins mentioned above. The breakdown of C3 and intermediate products are shown in Figure 20.4 and the receptors for these components in Figure 20.5.

C1Q RECEPTORS

C1q shares the same general structure with a family of proteins termed 'soluble defense collagens' that includes the 'collectins' (MBL, surfactant proteins A and D, conglutinin), and the ficolins. These proteins have collagen-like regions associated with globular recognition domains. The collectins have C-type lectin carbohydrate recognition domains. Ficolins also recognize acetyl groups on carbohydrates and other molecules using

fibrinogen-like recognition domains. The globular head groups of C1q bind to amino acid motifs on IgG, IgM, and pentraxins. In general, this group of proteins has broad recognition ability for both pathogen-associated carbohydrate patterns and for damaged or apoptotic cells. C1q and the soluble defense collagens share a receptor, C1qRp, to which they bind through their collagen-like regions.²⁸ C1qRp is expressed on phagocytic cells, endothelial cells, and platelets. On monocytes and neutrophils, binding of C1q, MBL, or SP-D to C1qRp does not directly induce phagocytosis, but can enhance Fc receptor and CR1-mediated phagocytosis of suboptimally opsonized targets. On endothelial cells C1qRp may contribute to the endothelial response to immune complexes.

CD35 (CR1), discussed further below, has separate binding sites for C3b, C4b, and C1q, facilitating binding to immune complexes or microorganisms with multiple complement components attached. CR1 also binds to MBL.

The $\alpha_2\beta_1$ integrin on mast cells, which binds to collagen and other matrix ligands, was recently reported to bind to C1q, MBL, and SP-A. The interaction of mast cells expressing $\alpha_2\beta_1$ integrin with opsonized *Listeria* resulted in C1q-dependent adhesion and secretion of interleukin (IL)-6.²⁹ Furthermore, mice deficient in the α_2 integrin subunit exhibited diminished neutrophil and IL-6 responses during peritonitis induced by *Listeria* or zymosan.

Other C1q binding proteins have been identified, notably calreticulin and gC1qbp. Neither of these are receptors in the classical sense, since they are not membrane proteins.²⁸ Calreticulin (CRT, cC1qR, collectin receptor) binds to the collagen-like regions of C1q, MBL, SP-A, and SP-D. Calreticulin is found in the endoplasmic reticulum, but is also found on the surface of macrophages and may be translocated to the cell surface during cell stress. Calreticulin lacks a transmembrane domain, but has been shown to contribute to the uptake of opsonized apoptotic cells opsonized with C1q, MBL, or SP-D by association with the α_2 -macroglobulin receptor, CD91.³⁰

Another intracellular protein, gC1qbp, is widely expressed and binds to the globular head groups of C1q. Secreted gC1qbp can inhibit C1 activation, suggesting a role as a regulatory protein.

COMPLEMENT RECEPTOR 1 (CD35, CR1)

There are five identified receptors for bound fragments of C3 and/or C4. CD35 (CR1) is a large protein composed of a linear string of CCPs, a transmembrane region, and a short intracytoplasmic domain. Different allelic forms of CD35 are found, the most common being composed of 30 CCPs with a molecular weight of 190 kDa. These CCPs are organized into groups of seven, creating structures termed long homologous repeats (LHRs), each of which contains a single binding site. The predominant allele of CD35 contains two binding sites for C3b, one for C4b and one for C1q. CR1 is found on human erythrocytes, monocytes and macrophages, neutrophils, B lymphocytes, a small percentage of T lymphocytes, eosinophils, follicular dendritic cells (FDC), and glomerular podocytes.

CD35 on primate erythrocytes provides a noninflammatory mechanism for clearing soluble immune complexes from the circulation. Although the number of receptors on each erythrocyte is low, the large number of erythrocytes provides the major pool of CR1 in the circulation. Soluble immune complexes that fix complement attach quickly to erythrocytes in the circulation, bypassing monocytes and neutrophils.

Fig. 20.5 Receptors for bound C3b and its cleavage products. Receptors shown are CD35 and CD21 composed of CCP (SCR) subunits, CD11b/CD18 (CR3), a β_2 integrin, and CR1g with 1 or 2 lg domains. The specificities of the receptors are: CD35 for C3b, C4b > iC3b; CR1g for iC3b > C3b; CD11b/CD18 for iC3b; CD21 for C3dg, C3d > iC3b. CD11c/CD18 (CR4) is similar to CD11b/CD18 and is not shown. Receptors are not drawn to scale. Their molecular weights are listed in Table 20.1.

These erythrocyte-bound complexes are taken to the liver where they are transferred to Kupffer cells expressing Fc and complement receptors and destroyed. The erythrocytes exit into the circulation to pick up more immune complexes. This clearance pathway is impaired in patients with systemic lupus erythematosus (SLE) due to decreased complement in the circulation, decreased CD35 on erythrocytes, and saturated Fc receptors in the liver and spleen.

CD35 on monocytes and neutrophils promotes binding of microbes with bound C3b and C4b, facilitating their phagocytosis through Fc receptors. CD35 can directly mediate uptake of microbes when phagocytic cells have been activated by chemokines or integrin interactions with matrix proteins.

CD35 is a member of the RCA family and has decay-accelerating and cofactor activity in addition to its function as a receptor. It differs from the membrane regulatory proteins DAF (CD55) and MCP (CD46) in its ability to bind to C3b and C4b extrinsically (on targets other than the cell expressing it), and in its cofactor activity for C3b processing. CD35 is the most effective cofactor for factor I cleavage of C3b and iC3b to the smallest covalently bound fragment, C3dg. C3dg is the major ligand for CR2 on B lymphocytes, described below. The cofactor activity of CD35 on B lymphocytes is believed to process bound C3b to C3dg, which lowers the threshold for B-cell activation through antigen-specific receptors.

COMPLEMENT RECEPTOR 2 (CD21, CR2)

CD21 (CR2) is also an RCA family protein composed of 15–16 CCPs. CD21 has a limited range of expression that includes B lymphocytes, FDC, and some epithelial cells. CD21 is specific for the smallest covalently bound C3 fragments, C3dg and C3d, and has weaker binding to iC3b. CD21 is also the Epstein–Barr virus receptor on B lymphocytes and nasopharyngeal epithelial cells and binds to CD23, a low-affinity IgE receptor.

CD21 on B lymphocytes serves a co-stimulatory role.³¹ It is expressed on mature B cells as a complex with CD19 and CD81 (TAPA-1). Co-ligation of CD21 and the B-cell antigen receptor induces the phosphorylation of CD19, activating several signaling pathways and strongly amplifying B-cell responses to antigen. This role of CD21 is believed to contribute to the strong adjuvant effect produced by attaching C3d to antigen.³²

COMPLEMENT RECEPTORS 3 AND 4

CR3 and CR4 are the β_2 -integrins commonly known as CD11b/CD18 (Mac-1) and CD11c/CD18. β_2 -integrins are large heterodimers found on neutrophils and monocytes with multiple roles in adhesion to endothelium and matrix molecules as well as direct recognition of microbial pathogens. The binding activities of β_2 -integrins are regulated by cellular activation often through chemokine receptors. Both CD11b/CD18 and CD11c/CD18 are expressed primarily on neutrophils, monocytes, and natural killer cells and bind to iC3b and, to a lesser extent, C3b.

CD11b/CD18 has been studied more extensively than CD11c/CD18. CD11b/CD18 expression, clustering, and conformation are all rapidly upregulated by chemokine activation of neutrophils, leading to increased responses to ligand.³³ CR3 plays an essential role in neutrophil attachment to and migration through activated endothelium to sites in inflammation and in the regulation of neutrophil apoptosis. Deficiency of the β_2 -chain (CD18) results in leukocyte adhesion deficiency, characterized by recurrent pyogenic infections and defects in inflammatory and phagocytic responses. Complement receptors CD11b/CD18 and CD11c/CD18 provide an essential function for the removal of microbial pathogens following complement activation, since C3b processing often occurs rapidly following deposition.

COMPLEMENT RECEPTOR OF THE IMMUNOGLOBULIN SUPERFAMILY (CRIg)

CRIg³⁴ is a newly identified receptor for iC3b and C3b found on Kupffer cells in the liver as well as other tissue macrophages, but absent from splenic macrophages, peripheral blood cells, bone marrow-derived macrophages, and monocyte/macrophage cell lines. Two alternative-spliced forms of human CRIg were identified with one and two Ig domains. The mouse receptor has a single Ig domain. CRIg is thought to function in the removal of C3b or iC3b-opsonized particles from the circulation by the liver.

C5A AND C3A RECEPTORS

During complement activation, the homologous proteins C4, C3, and C5 are each cleaved near the amino-terminus of the α -chains to release a soluble peptide fragment of approximately 8 kDa. These fragments are designated C4a, C3a, and C5a. C5a may also be generated locally by direct leukocyte protease cleavage of C5. These peptides are termed anaphylatoxins because of their ability to increase vascular permeability,

contract smooth muscle, and trigger the release of vasoactive amines from mast cells and basophils. C5a is 10–100-fold more active than C3a, which is much more (1000-fold) active than C4a. These peptides are also chemotactic: C5a is specific for neutrophils, monocytes, and macrophages, whereas C3a is specific for mast cells and eosinophils. Other biological activities of complement anaphylatoxins are summarized in Table 20.2.

Structurally the anaphylatoxins are compact structures consisting of multiple helices cross-linked by disulfide bonds with more flexible carboxy-terminal regions. The C-terminal peptide of C3a interacts with the C3aR and can reproduce C3a agonist activity. In contrast, C5a interacts with the C5aR at multiple sites. Serum carboxypeptidases cleave the C-terminal arginine from C5a, C3a, and C4a producing the *des Arg* forms. This inactivates C3a and C4a; however, C5a *des Arg* retains much of its biological activity.

The C5aR (CD88 and C5L2) and the C3aR are rhodopsin-type receptors with seven transmembrane-spanning domains.³⁵ The C4aR has not been cloned. The C5aR and C3aR are coupled to G-protein signaling. C5L2 is not G-protein-coupled and may serve as a regulatory decoy receptor limiting the inflammatory response to C5a. The C5aR is expressed at high levels on neutrophils and is also found on macrophages, mast cells, basophils, smooth-muscle cells, and endothelial cells. When C5a is generated locally, for example in an extravascular site of infection, it helps induce an acute local inflammatory response including vasodilation, edema, neutrophil chemotaxis, and activation of neutrophils and macrophages for enhanced phagocytosis and killing.³⁵ The inflammatory activities of C5a may also contribute to complement-mediated pathology in conditions such as sepsis, acute respiratory distress syndrome, and ischemia–reperfusion injury, making the C5a–C5aR interaction an attractive therapeutic target.

COMPLEMENT IN HOST DEFENSE AND IMMUNITY

COMPLEMENT IN HOST DEFENSE

Complement activation provides a coordinated response to infection that results in the opsonization of microbial pathogens and the attraction and activation of phagocytic cells to kill them. Complement-dependent opsonization is of greatest importance in infections with encapsulated extracellular bacteria, and individuals with deficiencies in antibody production, neutrophil function, or C3 share increased susceptibility to these organisms, including *Streptococcus pneumoniae* and *Haemophilus influenzae*. MBL deficiency is also associated with recurrent pyogenic infections in young children. In general, activation of complement by natural antibody or MBL results in C3b and iC3b deposition on these pathogens, overcoming the anti-phagocytic effects of the capsule. Phagocytic cells ingest and kill the organisms using CD35, CD11b/CD18, and CD11c/CD18 receptors in conjunction with other innate and Fc receptors. C5a signaling activates these receptors, leading to increased phagocytosis. Gram-negative bacteria are susceptible to complement-dependent lysis. This is evident in the increased incidence of disseminated neisserial infection in individuals deficient in C3, any of the MAC components, or properdin, as discussed below.

Table 20.2 Cellular targets and effects of complement anaphylatoxins

	Target	Effects
C3a, C5a	Mast cells, basophils	Degranulation, release of vasoactive amines: contraction of smooth muscle, increased vascular permeability
C3a	Eosinophils	Chemotaxis, degranulation
C5a	Endothelium	Increased adhesion of leukocytes, chemokine and cytokine synthesis
C5a	Neutrophils, monocytes/macrophages, eosinophils, basophils, astrocytes	Chemotaxis
C5a	Neutrophils, monocytes/macrophages	Priming: activation of receptors, assembly of NADPH oxidase; activation: degranulation, respiratory burst
C5a	Resident macrophages	Regulation of FcγR expression (↑ activating, ↓ inhibitory)
C5a	Hepatocyte	Acute-phase protein synthesis
C3a, C5a	Lymphocytes, antigen-presenting cells	Regulation of T-cell responses to antigen

COMPLEMENT IN INFLAMMATION

An essential function of complement in host defense is the coordination of the local inflammatory response. C5a is the most potent complement product in this activity.³⁵ Sublytic deposition of MAC on endothelial cells and platelets and C3a interaction with the C3aR also contribute to the proinflammatory effects of complement activation. As discussed below, these potent inflammatory fragments of complement, when generated in high amounts or targeted inappropriately, result in many of the disease-related deleterious effects of complement. Local production of C5a at a site of infection occurs either through local complement activation or through direct cleavage of C5 by tissue macrophages. This C5a is released and sets up a chemotactic gradient for neutrophils and macrophages. In addition C5a activates endothelial cells to express P-selectin and synthesize chemokines, including IL-8. Interaction of C5a with mast cells releases vasoactive amines, increasing endothelial permeability. Neutrophils and macrophages are “primed” by interaction of C5a with its receptor. Priming includes enhancement of chemotaxis, activation of phagocytosis through complement receptors, and assembly of the NADPH-oxidase that is required for effective killing of microbes after phagocytosis. C5a also prevents neutrophil apoptosis, prolonging survival and contributing to local accumulation. Together these actions result in the attraction and activation of potent anti-microbial cells and resolution of infection (Fig. 20.6).

PATHOGEN EVASION OF COMPLEMENT

Further evidence of the host defense function of complement is the association of complement evasion strategies with virulence. Pathogenic Gram-negative bacteria, such as *Salmonella*, have lipopolysaccharides with long O-polysaccharide side chains that promote rapid shedding of the MAC and prevent its insertion into the cell membrane. *Neisseria*

**Fig. 20.6** C5a in local host defense.

species have several factor H-binding components that help restrict alternative-pathway activation and protect against lysis. Group A and B streptococci and *Streptococcus pneumoniae* have cell surface components (M protein, Bac or beta, PspC, Hic) that bind to factor H and/or C4bp, restricting complement activation. Other organisms, including type 3 group B streptococci, elaborate sialic acid-containing capsules or cell walls to limit alternative-pathway activation.

Although complement deficiencies are not generally associated with viral infections, the importance of complement in host defense against viruses is suggested by the multiple strategies used by viruses to evade complement. Several viruses produce complement regulatory proteins, including vaccinia virus complement control protein, and herpes virus glycoprotein C, which facilitate breakdown of C3b and C4b. Some viruses, such as human immunodeficiency virus (HIV), incorporate complement regulatory proteins into the viral envelope, a strategy that is also used by other pathogens, such as *Schistosoma*.

There are also many examples of complement receptors and membrane regulatory proteins being exploited as receptors for pathogens to invade cells. Examples of these are summarized in reference 1, and include strategies of direct pathogen binding to receptors as well as deposition of C3 fragments followed by invasion through host C3 receptors.

ROLE OF COMPLEMENT IN ADAPTIVE IMMUNITY

Over the past 10 years there has been renewed interest in the role of the innate immune system in adaptive immune responses. The importance of complement in humoral immunity has been recognized since the observation by Pepys in 1972³⁶ that complement depletion of mice prior to immunization decreased antibody responses to thymus-dependent antigens. Further studies have shown that complement receptors CR1 (CD35) and CR2 (CD21) are also required. In humans these receptors are found together on B lymphocytes and FDC. CD35 is also expressed on a number of other cell types (described above), including erythrocytes and phagocytic cells.

Effects of complement on the humoral immune response

Results obtained by experimental manipulation of C3, C4 and their receptors in mouse models indicate roles for these complement components at multiple levels in the humoral immune response.³⁷ One caveat regarding these studies is that in the mouse CD35 and CD21 are alternative splice products of the same gene, and genetically deficient animals lack both receptors. In humans CD35 and CD21 are encoded by separate genes. The first role of CD35/CD21 is in B-cell development, indicated by a pronounced defect in B-1 cell development in CD35/CD21-deficient mice. B-1 cells are generally found outside lymphoid follicles, have a restricted repertoire, and are essential in the production of natural antibodies to pathogens, such as *S. pneumoniae*, and to self antigens exposed on damaged cells, such as phosphatidylcholine and DNA. Although the mechanism of this defect in CD35/CD21-deficient mice is unknown, these mice have an altered repertoire of natural antibody and B-1 cells. Decreased natural antibody may contribute to susceptibility to infection and autoimmune disease in hereditary complement deficiency (discussed below).

A second role for complement in the antibody response is the well-described function of CD21 as a co-receptor for the mature B-cell response to antigen.³¹ As described above, CD21 is associated with the signaling complex of CD19 and CD81 (TAPA-1) in the B-cell membrane. Co-ligation of CD21 with the B-cell antigen receptor occurs naturally when the antigen activates complement and covalently binds C3dg. This co-ligation of the B-cell receptor with CD21 greatly decreases the threshold for B-cell activation and blocks Fas-initiated apoptosis of B cells. B cells activated by complement-opsonized antigen have increased ability to present antigen as well as survival and proliferation during encounters with T-dependent antigens.

KEY CONCEPTS

USE AND EVASION OF COMPLEMENT BY PATHOGENS

Bacteria

- >> Block C1, C3b deposition
Streptococcus pneumoniae
- >> Block membrane attack complex membrane access
Salmonella
- >> Limit access of C3 to C receptors by capsules
Streptococcus pneumoniae
- >> Block alternative pathway activation by sialation
Streptococcus agalactiae (type III)
Neisseria
- >> Bind factor H, C4bp to limit complement activation
Streptococcus pneumoniae (Hic)
Streptococcus pyogenes (M protein)
Neisseria
- >> Use DAF, CD46 for attachment to cells
Streptococcus pyogenes (M protein)
Neisseria
Escherichia coli
- >> Use complement receptors for entry
Mycobacterium tuberculosis and CD11b/CD18 (CR3)

Viruses

- >> Express complement regulatory proteins
Herpes simplex virus (HSV) and glycoprotein C
Vaccinia and VCP
- >> Use membrane complement receptors to enter cells
Epstein-Barr virus and CD21 (CR2)
Measles virus, adenovirus, herpes virus 6, and CD46 (MCP)
Picornaviruses and CD55 (DAF)
- >> Use complement receptors for entry
Human immunodeficiency virus (HIV) and CD35 (CR1), CD11b/CD18 (CR3)

Parasites

- >> Express complement regulatory proteins
Schistosoma and CR1
- >> Take up complement regulatory proteins
Schistosoma and CD55 (DAF)
- >> Use complement receptors for entry
Leishmania and CD35 (CR1), CD11b/CD18 (CR3)

The expression of CD35 and CD21 on FDC is also important in the antibody response. FDC trap antigen in the germinal centers and provide selection of somatically mutated high-affinity B-cell clones. Antigen trapped on FDC also provides a source of long-term stimulation for maintenance of memory B cells. FDC use complement receptors (CD35 and CD21) and Fc γ R to trap and retain antigen for these functions. Expression of CD21 on both FDC and B cells is required for effective affinity maturation of the antibody response and for the development and maintenance of memory B cells.

Complement and T-cell activation

Recent studies in primary pulmonary infection with influenza indicate that C3-deficient mice have a defect in influenza-specific CD4 and CD8 T-cell priming.³⁸ CR1/2 deficiency had no effect. The mechanism is unknown, but may be more efficient uptake and presentation of C3-opsonized virus by APC through CR3 and CR4 or stimulation of T-cell responses through the C3aR.

Co-stimulation of human T cells *in vitro* through CD3 and CD46 leads to the development of T cells with a regulatory phenotype characterized by synthesis of IL-10 in the absence of other Th2 cytokines (IL-2, IL-4).³⁹ The induction of regulatory T cells was seen in response to both anti-CD46 cross-linking and natural ligands (C3b dimers, streptococcal M protein).

CD55-deficient mice showed enhanced T-cell responses to immunization and increased T-cell-dependent autoimmune disease. These effects were complement-dependent and apparently involve the loss of CD55 regulation of local complement synthesis by APC during cognate interactions with T cells. One postulated mechanism is that CD55 inhibits the generation of C3a and C5a by APC, preventing their interactions with C3aR and C5aR on T cells.⁴⁰ Complement anaphylatoxins C3a and C5a have many important effects in inflammatory diseases that include attraction and activation of inflammatory cells, as well as regulation of APC and T-cell responses. Examples of these will be discussed in the sections below on complement in disease.

ROLE OF COMPLEMENT IN CLEARANCE OF APOPTOTIC CELLS

Damaged tissue and dead and dying cells activate complement through several pathways. This may increase local inflammation and injury, as in ischemia/reperfusion injury and hemolytic-uremic syndrome (HUS) (discussed below). Complement activation by apoptotic cells contributes to their opsonization and clearance, and may prevent the development of autoimmunity. The deleterious consequences of complement activation following tissue damage are mainly attributable to alternative-pathway-dependent generation of C5a and the MAC,⁴¹ whereas the beneficial effects are dependent on early classical pathway components and innate recognition molecules.⁴²

Necrosis as occurs following ischemic tissue injury exposes phospholipids and mitochondrial proteins that activate complement directly or indirectly. The pathways are different depending on the tissue involved.⁴¹ For example, renal reperfusion injury appears to be initiated by the alternative pathway, possibly secondary to the loss of regulatory proteins on tubular epithelial cells. Intestinal ischemia-reperfusion injury is initiated by natural IgM antibodies and requires both the classical pathway for initiation, and the alternative pathway for injury. MBL and CRP-initiated

Fig. 20.7 Pathways of opsonization of apoptotic cells by complement. Innate recognition of apoptotic cells by natural immunoglobulin M (IgM), C-reactive protein (CRP), serum amyloid P (SAP), C1q, and mannose-binding lectin (MBL) is shown. Each reaction activates complement leading to opsonization by C3b and iC3b. In addition, C1q and MBL bind to collectin receptors, and CRP and SAP bind to Fc γ R on macrophages. Cytokine responses to apoptotic cells opsonized by complement include the anti-inflammatory cytokines, transforming growth factor- β (TGF- β) and interleukin-10 (IL-10).

complement activation have been proposed to contribute to myocardial reperfusion injury after coronary artery ligation.⁴³

Apoptotic cells are recognized by multiple receptors and opsonins.^{42,44} The association between early classical pathway deficiencies and SLE (see below) has been attributed to a failure of complement-dependent opsonization, resulting in accumulation of apoptotic cells and released autoantigens.^{2,45} Support for this hypothesis is provided by studies of mice deficient in C1q, IgM, or SAP, all of which develop autoantibodies against phospholipid and nuclear antigens characteristic of SLE, and by the therapeutic effect of CRP in mouse models of SLE.⁴ The role of complement in apoptotic cell recognition and uptake by macrophages is depicted in Figure 20.7. MBL, C1q, and SP-D bind to apoptotic cells and facilitate clearance through direct binding to collectin receptors as well as complement activation.^{30,42} Natural IgM antibodies, CRP, and SAP bind to phospholipids exposed on late apoptotic cells. All three proteins can also activate the classical pathway generating C1q, C4b, C3b, and iC3b ligands for complement receptors. CRP and SAP also directly opsonize apoptotic cells for uptake through Fc γ receptors.⁴ Phagocytosis of apoptotic cells generally induces anti-inflammatory cytokines, transforming growth factor- β (TGF- β) and IL-10.^{42,44}

Targeted activation of complement for opsonization

Interestingly, CRP and SAP also bind complement regulatory proteins, factor H and C4bp, which helps to limit complement activation to the deposition of opsonic components with little or no lysis or generation of C5a.^{46,47} This type of complement activation was also observed on acrosome-activated spermatozoa. In this case the classical pathway was activated by CRP from follicular fluid, resulting in bound C3b and iC3b that

are proposed to bind complement receptors on the egg and facilitate fertilization. Riley-Vargas and colleagues²² have proposed the acronym TRACS (targeted and restricted activation of the complement system) for this type of limited complement activation that occurs as part of normal processes such as the acrosome reaction, and the recognition and removal of ischemic tissue and apoptotic cells.

COMPLEMENT DEFICIENCIES

GENETICS AND INCIDENCE

Complete genetic deficiencies of complement proteins are rare, with an estimated combined prevalence of 0.03% for any inherited complete deficiency (excluding MBL deficiency) in the general population.⁴⁸ For most components, inheritance is autosomal and expression is codominant, so complete deficiency is homozygous recessive and heterozygotes express half levels. There are two C4 genes (C4A and C4B), so a range of partial deficiencies may be observed. All cases of C1-INH deficiency have been heterozygous, and properdin deficiency is X-linked. MBL is found in multiple allelic forms with different levels of expression ranging from 5 ng/ml to more than 5 µg/ml in plasma. Deficiencies specific to the lectin pathway are not detected by the screening assays described below, but may be determined by specific assays.⁷ A 10% incidence of MBL deficiency and a single case of MASP-2 deficiency have been described.

The most common clinical presentations of patients with complement deficiencies are recurrent infections with encapsulated bacteria, recurrent neisserial infections, and systemic autoimmune disease (Table 20.3). Populations with these disease manifestations have a much higher incidence of complement deficiency. For example, in white patients with SLE, the incidence of C2 deficiency is nearly 1%, 100-fold higher than in the general population. Screening of patients with autoimmune disease for complement deficiencies is useful, as these individuals are at higher risk for certain disease manifestations and may be at greater risk for infectious complications. Complement deficiency is found in as many as 20% of patients with recurrent disseminated neisserial infections. Evaluation of complement function is highly recommended in patients with recurrent or disseminated neisserial infections so that appropriate immunization and antibiotic prophylaxis can be instigated.

Complement deficiencies are most readily detected by hemolytic screening assays⁴⁸ – the CH₅₀ and AH₅₀, which determine the dilution of patient's serum needed to lyse 50% of erythrocytes sensitive to the classical (CH₅₀) or alternative pathway (AH₅₀). Deficiency of any C1 subcomponent, or any of the other classical pathway components (C2–C8) will result in little or no lysis in the CH₅₀ (CH₅₀ values less than 5%).⁴⁹ C9-deficient patients may have residual activity in this assay (CH₅₀ values less than 30%). Little or no lysis is observed in the AH₅₀ assay if factor D, properdin, or any of the components C3–C9 are deficient. Deficiency of factor B has not been described. By comparing the results in the two assays it is possible to narrow the search for the deficient component (Fig. 20.8). Hemolytic and antigenic assays may be done for each individual component to confirm the deficiency.

CLASSICAL PATHWAY DEFICIENCIES

Patients with deficiencies of early classical pathway components (C1, C4, C2) are most commonly identified as having systemic autoimmune disease, but are also at increased risk of infection. The primary infectious

agents in these patients are encapsulated bacteria, *Streptococcus pneumoniae*, *Hemophilus influenzae*, *Neisseria meningitidis*, and *S. agalactiae*, which rely on antibody and classical pathway opsonization for clearance.

C1 deficiency

C1-deficient patients most commonly lack C1q, but C1r or C1s deficiency also results in nonfunctional C1 and no classical pathway activity. Absence of C1q is highly associated with the development of SLE, with an incidence of 90%. It has been proposed that this association is related to defective clearance of apoptotic cells.⁴⁵ Apoptotic cells may be opsonized by IgM, or pentraxins leading to activation of the classical pathway, which may be initiated by IgM or pentraxin (CRP and SAP). Cells may also be cleared by direct C1q binding, leading to attachment and uptake through other phagocytic receptors, e.g., the phosphatidylserine receptor.² Other proposed mechanisms to account for the strong association between C1 and C4 deficiency (see below) and SLE include defective immune complex clearance and defective development and maintenance of B-cell tolerance.

C4 deficiency

There are two C4 genes, C4A and C4B, located within the major histocompatibility complex (MHC) on chromosome 5. The two forms of C4 have similar function, but different substrate preferences for the covalent bonding reaction that occurs on activation to C4b. C4A is more efficient in attaching to amino groups on proteins, such as immune complexes, whereas C4B is more efficient in attaching to carbohydrates. Complete C4 deficiency requires four null alleles and is rarely found, but is highly associated with SLE (75% incidence). Partial C4 deficiencies with one to three null alleles, however, are relatively common, found in up to 25% of individuals. Complete C4A deficiency is greatly over-represented in the SLE population. C4A deficiencies are found in about 1% of the general population and 10–15% of patients with SLE. Complete C4B deficiencies are more commonly associated with bacterial infections, suggesting that the

CLINICAL RELEVANCE

VALUE OF SCREENING FOR COMPLEMENT DEFICIENCIES

- >> Patients with infection due to complement deficiencies are much more likely to have recurrent infection
- >> Immunization and antibiotics should be considered as prophylactic strategies to diminish the risk of primary or recurrent infections in complement-deficient individuals
- >> Screening patients with autoimmune disease for complement deficiencies is important as these patients may be at increased risk for infectious complications. Antibiotic prophylaxis and immunization should be used where appropriate
- >> Patients with recurrent disseminated neisserial infection should be evaluated for deficiency of C3–C9 by CH₅₀ assay

Table 20.3 Clinical effects of complement deficiency

Deficient component	Resulting defect	Clinical associations
C1q, C1r, C1s, C4, C2	Inability to activate the classical pathway	Systemic lupus erythematosus
Factor D, properdin	Inability to activate the alternative pathway	Infection, <i>Neisseria meningitidis</i>
MBL, MASP-2	Decreased or absent ability to activate the lectin pathway	Recurrent childhood infection, pyogenic bacteria
C3	Lack of opsonization, inability to generate C5a and form the MAC	Recurrent childhood infection, <i>N. meningitidis</i> , <i>Streptococcus pneumoniae</i> , other encapsulated bacteria, autoimmune disease
Factor H, factor I, NeF	Lack of regulation of fluid-phase C3 convertases, severe acquired C3 deficiency	Infection, membranoproliferative glomerulonephritis
C5, C6, C7, C8, C9	Inability to form the MAC	Recurrent, disseminated neisserial infection
Serum carboxypeptidase N	Failure to control C3a, C5a, bradykinin	Recurrent angioedema, urticaria
C1 INH	Loss of regulation of C1 and kallikrein	Recurrent angioedema
Factor H, factor I, CD46	Lack of regulation of membrane C3 convertases	Atypical hemolytic-uremic syndrome, macular degeneration
DAF, CD59	Failure to regulate complement activation on autologous cells	Paroxysmal nocturnal hemoglobinuria

C1 INH, C1 esterase inhibitor; DAF, decay-accelerating factor; MAC, membrane attack complex; MASP, MBL-associated serum protease; MBL, mannose-binding lectin; NeF, nephritic factor.

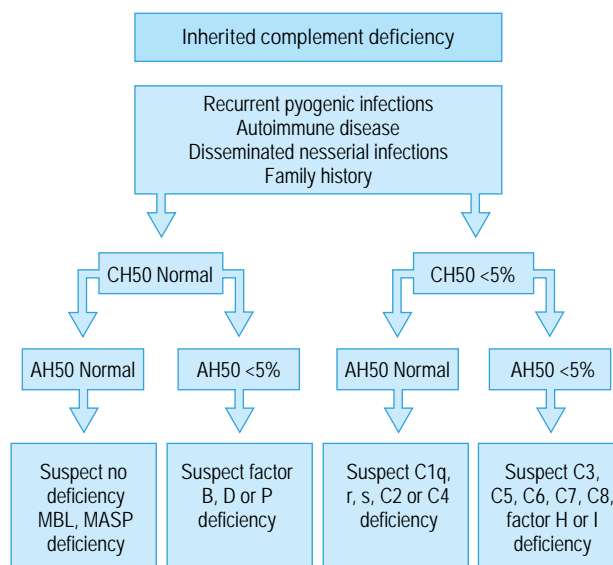

functionally different C4 genes contribute differently to host defense and autoimmunity.

C2 deficiency

The gene for C2 is also located within the MHC. C2 deficiency is the most common complete complement deficiency, with about 0.01% incidence in the population. About half of C2-deficient individuals are clinically normal. The remaining individuals have recurrent pyogenic infections and/or rheumatologic diseases. The most common infectious agents are *S. pneumoniae*, *H. influenzae*, *N. meningitidis*, and *S. agalactiae*. Infections are invasive and mainly found in childhood, suggesting that the immune defect may be overcome by development of acquired immune defenses.⁵⁰ The rheumatologic diseases include SLE (15%) vasculitis, polymyositis, and Henoch-Schönlein purpura. The SLE associated with C2 deficiency has some features that distinguish it from other SLE, including equal expression in males and females, early onset, increased photosensitivity, decreased renal disease, lower frequency of anti-dsDNA antibodies, and higher frequency of anti-SSA/Ro and anti-C1q antibodies.⁵⁰

LECTIN PATHWAY DEFICIENCIES

MBL deficiency was originally found as a serum defect in opsonization of yeast in pediatric patients with recurrent infections. There are multiple MBL polymorphisms in the population both in the promoter and coding regions, and MBL deficiency is common (estimated to be 14% in the

C9 deficiency may have up to 30% normal CH50 with low AH50

Fig. 20.8 Flow chart for the evaluation of inherited complement deficiencies using hemolytic screening assays for the classical (CH₅₀) and alternative pathways (AH₅₀). For each assay, the entire activation pathway including the membrane attack complex (MAC) is required for lysis.

normal Swedish population).⁵⁰ In addition to the association of MBL deficiency in children with recurrent infections, there is a two- to three-fold increased frequency of MBL deficiency in SLE and these individuals have more frequent and more severe infections during the course of their disease. Serious infectious complications are also more frequent in the subgroups of cystic fibrosis and rheumatoid arthritis (RA) patients that have MBL deficiency.⁴⁸

A single homozygous MASP-2 deficiency has been reported.⁷ The patient was asymptomatic until the age of 13, when he was diagnosed with ulcerative colitis. Additional autoimmune manifestations developed along with recurrent severe infections with *S. pneumoniae*.

■ ALTERNATIVE-PATHWAY DEFICIENCIES ■

Individuals with complete deficiencies of factor D or properdin have been reported. Factor D-deficient patients have presented with recurrent infections due to *Neisseria* and other organisms. Properdin deficiency is X-linked and patients most commonly have severe childhood infections with *N. meningitidis*.

C3 DEFICIENCIES

C3 is central to all three complement activation pathways. Nineteen families have been reported with primary inherited deficiency of C3.⁵¹ The most common presentation is with recurrent life-threatening infections in early childhood (before the age of 2), sometimes followed by immune complex disease. The infections observed are primarily respiratory tract infections (48%) and meningitis (34%) with a variety of pathogens, especially encapsulated bacteria. The organisms most often involved are *Neisseria meningitidis* and *Streptococcus pneumoniae*, but other encapsulated Gram-negative and Gram-positive bacteria have also been observed. Recurrent infections are seen in more than half of C3-deficient patients. This clinical presentation is similar to that seen in hypogammaglobulinemia. C3-deficient individuals may develop renal disease (26%), including membranoproliferative and mesangiocapillary glomerulonephritis and autoimmune disease (26%), most commonly SLE.

Acquired C3 deficiency: genetic deficiencies of factor H and I, C3 and C4 nephritic factors

Factors H and I are required to control the fluid-phase alternative-pathway C3 convertase. Complete deficiency of either protein results in C3 cleavage and depletion to very low levels. C5, factor B, and properdin levels may also be reduced. The clinical presentation of patients with factor H or factor I deficiency resembles that of primary C3 deficiency.⁵¹ The highest disease association is recurrent infection with *N. meningitidis* and *S. pneumoniae*, and there is also an increased incidence of SLE. Factor H deficiency is more commonly associated with renal disease than C3 or factor I deficiency (73% of factor H-deficient individuals compared to 13% of factor I-deficient and 26% of C3-deficient individuals).

Nephritic factors (NeF) are autoantibodies specific to classical and alternative-pathway C3 convertases (C4b2a or C3bBb) or the alternative-pathway C5 convertase that stabilize these enzyme complexes and prevent normal regulatory control. The alternative-pathway C3NeF induces

unregulated complement activation, resulting in acquired C3 deficiency. NeF are most associated with membranoproliferative glomerulonephritis (MPGN) type II. C3NeF is also associated with partial lipodystrophy, a condition in which fat is lost from the waist upward.

DEFICIENCIES OF COMPLEMENT RECEPTORS

Deficiencies of CR1 (CD35) and CR2 (CD21)

Complete genetic deficiencies of CR1 or CR2 have not been reported. However, partial deficiencies of CR1 on erythrocytes, B lymphocytes, and polymorphonuclear leukocytes and of CR2 on B lymphocytes have been reported in SLE patients. Decreased CR1 on erythrocytes may be acquired as a result of immune complex clearance. CR2 has been identified as a lupus susceptibility gene in a lupus-prone strain of mice.³⁷

Leukocyte adhesion deficiency (LAD): CR3 and CR4 deficiency

Leukocyte adhesion deficiency (LAD: Chapter 21) is a syndrome caused by mutations of the common β_2 -integrin chain, CD18, found in LFA-1, CR3, and CR4. Defects are related to adhesion and activation of phagocytic cells and the clinical presentation includes childhood infections with pyogenic bacteria.

DEFICIENCIES OF REGULATORY PROTEINS

Hereditary angioedema: C1 INH deficiency

Hereditary angioedema (HAE) is found in individuals with heterozygous deficiency of C1-INH. Complete genetic deficiency of C1-INH has never been reported, and HAE is the only complement deficiency with an autosomal dominant pattern of inheritance. C1-INH is a serine protease inhibitor (serpin) with regulatory activity for C1r, C1s, MASP-1, and MASP-2 of the complement system, factor XII (Hageman factor), and kallikrein of the contact system, factor XI and thrombin of the coagulation system, and plasmin and tissue plasminogen activator (tPA) of the fibrinolytic system. Although previous studies implicated a C2 product (C2 kinin) as a mediator, more recent information, including studies in a C1-INH-deficient mouse model, indicate that bradykinin is the primary biological mediator of angioedema in HAE.^{52, 53} In the more common form of HAE (type I, 85% of patients), reduced synthesis of C1-INH is found (5–30% of normal), along with decreased serum C4 and C2. In type II HAE, an abnormal C1-INH is synthesized, making antigenic levels normal or elevated with reduced functional activity and decreased C4 and C2. Clinically, type I and type II HAE are indistinguishable.

HAE presents in childhood or adolescence as recurrent episodes of swelling that are subcutaneous and/or submucosal, nonpainful, nonpruritic, and nonpitting.⁵⁴ Urticaria is not present. Episodes are self-limited, usually peaking at 24 hours and resolving over 2–5 days. Attacks are variable in frequency, severity, duration, and location, and initiating factors are poorly understood. The most common areas involved are the extremities, face, genitals, respiratory tract, and gastrointestinal tract. Intestinal attacks are often associated with vomiting and diarrhea and are extremely painful. Laryngeal attacks may result in life-threatening respiratory obstruction. Laryngeal attacks are 50-fold less frequent than abdominal attacks and 70-fold less frequent than skin attacks, but the

overall lifetime incidence of laryngeal edema is 70%. Recurrent attacks continue throughout the life of the patient and may involve multiple sites or progress from one site to another.

Diagnosis of HAE is suggested by family history and clinical findings.⁵⁴ Confirmation is based on decreased C1-INH functional activity (< 10–35% of normal). It is important to note that, although C1-INH protein is decreased in type I HAE, it can be normal or even elevated in type II HAE. C4 levels are below normal in 95% of HAE patients. Acquired forms of C1-INH deficiency have been described, usually in elderly patients with lymphoproliferative diseases. These may be caused by autoantibodies to C1-INH and are distinguished from HAE by a lack of family history and decreased C1q, as well as C4. A small percentage (0.1–0.5%) of hypertensive patients treated with angiotensin-converting enzyme (ACE) inhibitors will experience angioedema as a result of elevated bradykinin levels, and ACE inhibitors should not be given to patients with HAE.

Management of HAE patients includes long-term prophylaxis, short-term prophylaxis, and treatment of acute attacks.⁵³ International consensus guidelines for diagnosis and management are given in Bowen et al.⁵⁴ Long-term therapy should be considered in patients with frequent attacks or a history of serious upper-airway episodes. Long-term therapy may be provided by attenuated androgens, such as danazol and stanozolol, which increase serum concentrations of normal C1-INH in both type I and type II HAE. The lowest dose of androgen that is clinically effective is used because of undesirable side effects. Symptomatic benefit is usually achieved at doses that are not sufficient to restore C1-INH levels. Treatment with attenuated androgens generally increases C4 protein levels and markedly reduces both the frequency of spontaneous attacks and the incidence of oral surgery-induced laryngeal edema. Anti-fibrinolytic therapy with epsilon aminocaproic acid (EACA) or tranexamic acid may be used to control HAE in patients who do not tolerate anabolic androgen therapy.

Treatment with higher doses of danazol or tranexamic acid is also useful for short-term prophylaxis 5–10 days prior to dental procedures or surgery. Infusion of fresh frozen plasma several hours before the procedure may also be effective. Although currently not licensed in the USA, C1-INH concentrates have proven effective in several case series studies for short-term prophylaxis.

Treatment of acute attacks with epinephrine, antihistamines, corticosteroids, or androgens is not effective. Anti-fibrinolytic therapy with high-dose EACA or tranexamic acid has been used, as has infusion with C1-INH concentrate or fresh frozen plasma. The efficacy of EACA therapy is currently supported only by anecdotal evidence and neither tranexamic acid nor C1-INH concentrate is licensed in the USA. Infusion of fresh frozen plasma carries a demonstrated risk of worsening the attack. In the absence of effective therapeutics, management of acute attacks is focused on symptomatic control.⁵³ Abdominal episodes may require fluid replacement and control of pain and nausea. Pharyngeal attacks are the most life-threatening and require hospitalization with careful airway monitoring and intubation if needed. Several new therapeutic agents are in development for acute episodes of HAE. These include recombinant human C1-INH, recombinant kallikrein inhibitor, and a bradykinin receptor antagonist.^{53,55}

Paroxysmal nocturnal hemoglobinuria: DAF and CD59 deficiency

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare acquired disorder in which a somatic mutation in the *Pig-A* gene in a clone of bone marrow stem cell results in defective synthesis of GPI-anchored proteins.⁵⁶

PNH is characterized clinically by intravascular hemolysis with periodic hemoglobinuria and venous thrombosis. DAF and CD59 are GPI-anchored complement regulatory proteins expressed on erythrocytes, and PNH erythrocytes are highly susceptible to lysis. Studies of individuals with isolated DAF and CD59 deficiencies indicate that hemolysis is more highly associated with CD59 deficiency. The basis for thrombosis in PNH is poorly understood.

Control of localized complement activation: atypical hemolytic-uremic syndrome, age-related macular degeneration

HUS is a rare disease characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. 'Typical' HUS is found in children and is caused by *Escherichia coli*, mainly 0157:H7, producing a shigalike toxin. Atypical HUS affects older children and adults and is not associated with infection. Recently, mutations in complement regulatory proteins, factor H, factor I, or CD46 have been identified in approximately 50% of patients with atypical HUS.⁵⁷ The factor H mutations associated with HUS are clustered in the C-terminal end of the molecule in CCP20, a region that is required for factor H binding to polyanions and endothelial cells. The ability of factor H to regulate fluid-phase alternative-pathway activation is not affected and C3 levels are normal. These findings have led to the hypothesis that local complement regulation is essential for preventing renal disease following endothelial cell injury, and that factor H acts locally after binding to exposed matrix or damaged endothelium. Factor H and the membrane protein CD46 are both cofactors for factor I-mediated cleavage of C3b.

An additional factor H polymorphism (Tyr/His⁴⁰²) identified by genetic screening has been shown to be associated with the development of age-related macular degeneration (AMD), a major cause of blindness in the elderly.⁵⁸ This polymorphism is located in CCP7 in a region of factor H that binds heparin and CRP.⁴⁷ As is the case for the mutations associated with HUS, this region of factor H is not required for regulation of the fluid-phase alternative-pathway convertase. AMD develops when abnormal deposits of protein, termed drusen, form in the retina. Recent findings support the view that the local inflammatory response, including complement activation with MAC deposition, damages the retina leading to vision loss. Additional genetic analyses identified protective factor H variants as well as protective and high-risk polymorphisms in the factor B gene. Although complement factors are not the only genes linked to AMD, they are estimated to account for more than 50% of cases. These findings may lead to the development of new therapeutics that could provide protection from a very common form of age-related visual loss.

COMPLEMENT IN DISEASE

MEASUREMENT OF COMPLEMENT IN A CLINICAL SETTING

Laboratory tests for complement include functional assays for the classical pathway (CH₅₀), the alternative pathway (AH₅₀), and the lectin pathway.^{48, 49} Functional and antigenic assays for each of the individual components are available in specialty laboratories. The CH₅₀ is a hemolytic assay in which sheep erythrocytes sensitized with

rabbit antibody are incubated with dilutions of the patient's serum. The titer is the dilution at which 50% of the sheep erythrocytes are lysed. The CH₅₀ requires all of the classical pathway and terminal components (C1–C9). A comparable assay for the alternative pathway uses a buffer that blocks classical pathway activation and rabbit erythrocytes in place of sensitized sheep erythrocytes. Rabbit erythrocytes spontaneously activate the human alternative pathway and are lysed in the assay. The AH₅₀ requires all of the alternative pathway and terminal components (factor B, D, P, C3–C9). The combined use of the CH₅₀ and AH₅₀ is the most effective screening method for genetic deficiencies of complement components. Complete deficiency will generally result in titers of < 5% in one or both assays. Because C3–C9 are common to both pathways, the combined results of the two assays can rapidly determine whether the deficiency is one of these shared components, one of the unique classical pathway components (C1, C2, C4) or one of the alternative-pathway components (factor B, D, properdin) (Fig. 20.8). Properdin deficiency results in low, but not absent, lysis in the AH₅₀, and C9-deficient patients may have values up to 30% of normal in the CH₅₀. Deficiencies of factor H and I and nephritic factors often result in very low C3 levels leading to reduced titers in both assays.

Lectin pathway function (and MBL deficiency) is determined using an ELISA in which the patient's serum is placed into wells coated with mannan. Binding MBL and activation of the lectin pathway results in the deposition of C4b and C4d that are detected with monoclonal antibodies. MBL levels may also be determined antigenically.

Heterozygous C1-INH deficiency as described above is associated with the clinical syndrome HAE.⁴⁹ The diagnosis may be made based on clinical findings and family history. C1 INH activity is reduced in these patients and C4 protein is also low in 95% of patients, especially during attacks of edema. In type I HAE (85% of cases), C1 INH protein levels are low, but in type II HAE (15% of cases), an abnormal C1 INH protein is made and antigenic levels are normal or elevated. There is an acquired form of C1 INH deficiency associated with lymphoma in which low C1 INH is accompanied by decreased C1q as well as C4 and C2.

Complement levels may also be decreased in diseases or conditions in which complement is activated, leading to consumption.⁴⁸ In contrast to genetic deficiencies, complement consumption characteristically results in low, but not absent, functional activity. In addition, multiple components of one or more pathways are expected to be low, and these decreased levels of complement are often correlated with disease activity. The most commonly used and most readily available complement tests are C3 and C4 protein and the CH₅₀. Diseases accompanied by classical pathway activation result in decreased CH₅₀, C4, and C3 levels. The alternative pathway is spared. These are primarily immune complex-associated diseases, both autoimmune and infectious, and are listed in Table 20.4. In addition 20% of cases of acute renal allograft rejection are associated with decreased CH₅₀ and C2. Another cause of selective classical pathway activation is essentially a laboratory artifact in which clotting of the blood sample is associated with consumption of the early classical pathway. Plasma CH₅₀, C3, and C4 levels are all normal, but serum CH₅₀ values are markedly decreased.

The alternative pathway is activated in gram-negative sepsis, post-streptococcal glomerulonephritis, MPGN, IgA nephropathy, factor H or factor I deficiency, and PNH. Laboratory values may show decreased C3 with decreased or normal CH₅₀, and normal C4 levels (Table 20.4). Alternative-pathway activation is not always reflected in decreased C3,

CLINICAL RELEVANCE

COMPLEMENT TESTS FOR DIAGNOSIS AND MONITORING OF SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

- >> Decreased C3 and C4 are associated with increased severity of disease, and especially with lupus nephritis
- >> On serial observation decreased C3 and C4 levels may predict flare
 - Note: C4 reductions can precede C3 reductions
- >> Remission after treatment of lupus often shows return to normal levels of C4, followed by increases in C3
 - Note: SLE patients with partial C4 deficiency may have persistently low C4 levels
- >> CH₅₀ levels also decrease with flares of lupus
- >> Decreased CH₅₀ levels are associated with partial complement deficiencies
- >> Complete absence of CH₅₀ implies the existence of a hereditary deficiency of one of the classical complement pathway components (C1–C9)

because C3 is found at the highest concentration of all complement components and is an acute-phase reactant with elevated synthesis during disease states.

In clinical practice evaluation of complement levels may be useful in a variety of circumstances. Initial consideration of complement deficiency may be appropriate in patients presenting with autoimmune or infectious diseases (Table 20.3). The complement profile may also be helpful in differential diagnoses (Table 20.4). Monitoring complement levels is used to follow disease activity in SLE patients. Low complement levels are a strong predictor of renal involvement and also an indicator of response to therapy in SLE.

ROLE OF COMPLEMENT IN SPECIFIC IMMUNOLOGICAL DISEASES

The following sections briefly describe contributions of complement activation to the pathogenesis of immunological diseases. Emphasis is given to conditions in which animal models have helped to define the relative roles of different pathways and activities of complement. A general concept emerging from current research in this area is that most of the pathogenic effects of complement depend on generation of C5a and MAC. Further, it is becoming recognized that, regardless of the initial activation mechanism, alternative-pathway amplification is needed to produce sufficient quantities of these mediators to cause disease.

Systemic lupus erythematosus (Chapter 51)

Complement plays a dual role in SLE. There is a strong association of genetic deficiencies of C1, C4, C2, and C3 with SLE, indicating a protective role. Three complement-dependent mechanisms have been proposed: (1) complement-dependent clearance of immune

Table 20.4 Complement test interpretation

Pathway	CH ₅₀	C4	C3	Related diseases
Classical	↓	↓	↓	SLE, IC disease, cryoglobulinemia, SBE
Alternative	↓	N	↓	Post-streptococcal GN, MPGN, IC disease
Fluid-phase activation of classical pathway	↓	↓	N	HAE, cryoglobulinemia, hypergammaglobulinemia
Fluid-phase activation of alternative pathway	↓	N	↓	Factor H or I deficiency
Acute-phase response	↑	↑	↑	Chronic inflammation in the absence of IC
Sample processing errors, coagulation-associated activation	↓	N	N	
Biosynthetic defects in complement proteins	↓	N	↓	Severe liver disease, decreased C3, C6, C9

GN, glomerulonephritis; HAE, hereditary angioedema; IC, immune complex; MPGN, membranoproliferative glomerulonephritis; SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus.

complexes; (2) an essential role for complement in the development and maintenance of self-tolerance in B lymphocytes; and (3) a requirement for complement in the clearance of apoptotic cells and potential autoantigens released from such cells. On the other hand, complement activation is believed to play a pathogenic role in tissue damage induced by autoantibodies in SLE. There is evidence for complement activation in SLE skin and renal lesions as well as in autoantibody-mediated hemolytic anemia and thrombocytopenia. In mouse models of SLE genetic deficiency or blockade of alternative-pathway activation is protective, whereas deficiency of C4 exacerbates autoimmunity and disease.⁴¹

The pathogenesis of SLE is due in large part to the inflammatory response to immune complexes formed by autoantibody binding to antigens from dead and dying cells. The Arthus reaction is often used to study the inflammatory response to passively administered IgG antibody and antigen (usually ovalbumin) independent of autoimmune disease. The response is FcγR-dependent and includes increased vascular permeability with edema and rapid influx of neutrophils into the site. Depending on the route of injection, the Arthus reaction can be elicited in the skin, lungs, or peritoneum, with some differences in cells and effector pathways. Recent findings have shed new light on a long-standing controversy regarding the roles of complement and FcγR in the Arthus reaction. In the current model C5a has an essential role, not as a neutrophil chemoattractant, but as a modulator of FcγR expression on resident macrophages.⁵⁹ C5a may be generated through immune complex-initiated complement activation or directly from C5 by proteolytic cleavage. C5a binding to the C5aR makes resident macrophages responsive to immune complexes by increasing expression of stimulatory FcγR and decreasing expression of inhibitory FcγRIIb. This pathway is likely to apply to lupus nephritis where pathogenesis requires stimulatory FcγR, is increased in the absence of FcγRIIb, and can be treated by blocking C5 cleavage.

Anti-phospholipid syndrome (Chapter 61)

Anti-phospholipid syndrome is characterized by anti-phospholipid antibodies, recurrent fetal loss, vascular thrombosis, and thrombocytopenia. Anti-phospholipid antibodies are found in 50% of lupus patients and thrombotic events occur in about half of these patients. Anti-phospholipid antibodies found in patients without SLE have similar clinical consequences. Disease pathogenesis has been attributed to procoagulant effects of anti-phospholipid antibodies. A mouse model was recently described in which injection of pregnant mice with human IgG anti-phospholipid antibodies resulted in fetal loss and wasting.⁴¹ In this model complement is required for pathogenesis and treatment with complement inhibitors is protective. Studies in the mouse model are consistent with initial complement activation by anti-phospholipid antibodies bound to the decidua, followed by C5a generation and recruitment of neutrophils. The alternative as well as the classical pathway was required for pathology. Interestingly, C3 deposition in the decidua was decreased if neutrophils were depleted, suggesting an amplification pathway mediated either by tissue damage or by neutrophil release of complement components.

Rheumatoid arthritis (Chapter 52)

Patients with RA generally have normal or elevated complement values systemically. There is, however, evidence for local complement activation in joint fluid, in synovium, and in rheumatoid nodules. Complement activation products in the joint are not specific to RA, but are also found in patients with osteoarthritis, SLE, Reiter's syndrome, and gout. Concentrations of C3a and C5a in joint fluid are higher in RA than in other types of arthritis. An important role for complement activation in the pathogenesis of RA is suggested by studies in two animal models – collagen-induced arthritis and the K/BxN-derived antibody transfer

model. In the first model, inflammatory joint disease was ameliorated by treatment with an antibody to C5 that blocks its cleavage, preventing generation of C5a and the MAC. In the second model, disease was prevented by genetic deficiency of factor B, but not C4, indicating an essential involvement of the alternative pathway.⁴¹

Vasculitis (Chapter 59)

Human vasculitides encompass a spectrum of disease mechanisms and clinical manifestations. Some, such as giant-cell arteritis and the anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitides, Wegener's granulomatosis, microscopic polyangiitis, and Churg–Strauss syndrome, are not associated with local complement deposition or evidence of systemic complement depletion. In others, particularly those with circulating immune complexes, C3b, MAC and/or alternative-pathway components are deposited in lesions and complement profiles consistent with activation are found (Table 20.4). Classical pathway activation is found in polyarteritis nodosa, hypersensitivity vasculitis, rheumatoid vasculitis, SLE vasculitis, and mixed cryoglobulinemia. The vasculitis of Henoch–Schönlein purpura has features of alternative-pathway activation.

Glomerulonephritis (Chapter 67)

Complement activation is evident in most types of glomerulonephritis, with the site and pathway of activation dependent on the site of immune complex or autoantibody deposition.⁶⁰ Alternative-pathway activation is associated with IgA nephropathy, post-streptococcal glomerulonephritis, and MPGN type II. In IgA nephropathy, C3, properdin and the MAC co-localize with IgA in glomerular mesangium. Earlier studies demonstrated activation of the alternative pathway by aggregated IgA. More recent results have implicated activation of the lectin pathway in IgA nephropathy.⁶¹ In a recent analysis of 60 renal biopsies from patients with IgA nephropathy, 25% showed deposition of MBL, along with L-ficolin, MASP, and C4d, indicating activation of the lectin pathway.⁶² Glomerular deposition of MBL was associated with greater histological damage and higher proteinuria.

MPGN is a chronic progressive form of glomerulonephritis characterized by endocapillary proliferation and thickening of glomerular capillaries producing enlarged glomerular tufts. MPGN is divided into three histological groups, designated type I, II, and III based on electron microscopy of the glomerular lesion. Complement activation is present in all forms of MPGN with decreases in circulating levels and the presence of C3 on biopsy. MPGN type II differs from the other two forms in that serum levels of C4 are not decreased and renal biopsies do not usually demonstrate IgG or C4 deposition. MPGN type II is associated with three conditions that lead to unregulated alternative-pathway activation, factor H deficiency, inhibitory antibodies to factor H, and C3NeF.^{51, 60} Complete factor H deficiency is rare, but strongly associated with renal disease (73% of cases), suggesting that unregulated alternative-pathway activation can damage the kidney. Factor H-deficient pigs and mice also develop MPGN that in mice could be alleviated by combined deletion of factor B.⁵¹ C3NeF is an autoantibody that binds to the alternative-pathway C3 convertase (C3bBb), preventing its decay and regulation by factor H and I. C3NeF is found in as many as 80% of patients with MPGN type II.

In glomerulonephritis secondary to immune complex disease, such as SLE and MPGN type I, complement activation is primarily by the

classical pathway and C4 is found deposited along with C3 and IgG in glomerular deposits. Complement activation contributes to disease by attracting and activating inflammatory cells through C5a and by direct damage to cells through MAC. Pathology due to inflammatory cell infiltration is predominant when subendothelial immune complex deposition and complement activation occur. Subepithelial deposits are associated with membranous disease, characterized by minimal inflammation, but direct damage to podocytes by MAC. In the Heymann nephritis model of human membranous nephropathy, there is strong experimental evidence that MAC insertion into glomerular epithelial cells is responsible for proteinuria and beneficial effects can be seen with complement activation antagonists and anti-C5 antibody.

Asthma (Chapter 39)

Asthma is a chronic inflammatory disease of the lung in which Th2 responses to environmental allergens frequently play a critical role. The development of mice deficient in receptors for C3a and C5a has led to a new understanding of the roles of the complement anaphylatoxins in asthma.⁶³ Several studies demonstrated a correlation between C3a and C5a release in asthmatic lungs and the influx of eosinophils and neutrophils. C3-deficient and C3aR-deficient mice were protected from development of acute bronchoconstriction, airway inflammation, and airway hyperresponsiveness. C5a inhibition had similar effects on the response to challenge in an established allergic environment. However, in contradiction to these findings, C5 deficiency was genetically linked to susceptibility to experimental allergic asthma. Further studies found that C5a signaling (most likely through the C5aR on pulmonary dendritic cells) during initial pulmonary exposure to allergen decreased Th2 cytokine and IgE production, thereby preventing the initiating of the allergic response.⁶³

Ischemia/reperfusion injury

Ischemia/reperfusion (I/R) injury refers to injury induced by inflammatory mediators, such as reactive oxygen intermediates produced by activated neutrophils, following the reperfusion of hypoxic tissue. Different pathways of complement activation may be important in different sites of injury, possibly due to differences in expression of complement regulatory proteins.⁴¹ The complement mediators of tissue injury are C5a and MAC acting locally, and in some cases C5a acting systemically. In experimental renal I/R injury and in human tubular necrosis, the alternative pathway appears to be directly activated and neither antibody nor the classical pathway are required. However, in intestinal I/R injury, the classical pathway as well as the alternative pathway is required and a natural IgM antibody to a newly exposed antigen on damaged endothelium initiates complement activation. In coronary artery ligation/reperfusion models, innate recognition of epitopes on ischemic tissue by MBL and CRP leads to classical pathway activation.

Neurological disease

Complement is found in the central and peripheral nervous system. In the central nervous system complement enters from the blood when the blood–brain barrier is impaired. Low levels of hemolytic complement (0.25% of serum levels) can be measured in the cerebrospinal fluid if care is taken to stabilize it with gelatin during storage. Complement proteins

and regulatory proteins are synthesized by glial cells and astrocytes and synthesis is enhanced by inflammatory cytokines. There is evidence both from human multiple sclerosis (Chapter 65) and the animal model, experimental allergic encephalitis (EAE), that complement activation with the generation of the MAC contributes to the demyelination in these diseases. Generation of the MAC can lead to oligodendrocyte death, generation of inflammatory mediators, or a repair process in which myelin synthesis is decreased. Complement activation on myelin and oligodendrocytes is initiated by anti-myelin antibodies or directly by myelin through the classical pathway. There is evidence of MAC formation in the cerebrospinal fluid of patients with multiple sclerosis, and complement depletion, inhibition, and genetic deficiency are protective in rat and mouse models of EAE.

There is evidence of complement activation in degenerative neurological conditions such as Alzheimer's disease.⁶⁴ In Alzheimer's disease neurofibrillary tangles and senile plaques composed of β -amyloid and other proteins develop, resulting in neuronal loss and dementia with progressive loss of cognitive function. Complement activation products C1q, C4, C3, and MAC components, as well as clusterin and vitronectin, are found deposited in areas of amyloid, suggesting classical pathway activation. Peptides derived from β -amyloid were shown to activate C1 directly by binding to the collagen-like domain. SAP, a component of all types of amyloid, including β -amyloid, activates the classical pathway as well. There are limited data on the role of complement in Alzheimer's disease pathogenesis, with some studies reporting enhanced disease following complement inhibition and another finding decreased inflammatory changes and neuronal degeneration C1q deficiency.

COMPLEMENT-BASED THERAPEUTICS

The multiple roles of complement in inflammatory and autoimmune diseases make it an attractive target for therapeutic intervention. Recombinant complement inhibitors, inhibitory monoclonal antibodies and peptide-based receptor inhibitors have been developed to block complement effects.⁶⁵ As described above, complement has many beneficial effects in host defense and the adaptive immune response. The detrimental effects of complement activation are for the most part

associated with C5a and the MAC.⁴¹ Thus targeting either the generation of C5a or the C5aR might be expected to control inflammation while maintaining other important functions such as opsonization. An anti-C5 monoclonal antibody (eculizumab) that prevents its cleavage was effective in murine lupus and Heymann nephritis.⁶⁶ In human trials, eculizumab was of benefit in patients with PNH, but had no effect on urinary protein excretion in human membranous nephropathy. C5a inhibitory peptides (C5aRa) are effective in a number of inflammatory models in animals and have potential in the treatment of sepsis, reperfusion injury, and asthma.³⁵ Other approaches that are being developed will target complement regulatory proteins to specific cell or tissue targets.⁶⁵ This chapter covers our current concepts of the role of complement in disease. As complement has been the object of increasing importance in a variety of inflammatory diseases, it is likely that further research will establish new complement-based therapeutic agents for additional applications.

CLINICAL RELEVANCE

COMPLEMENT INHIBITORS AS THERAPEUTIC AGENTS

- >> Soluble regulatory proteins: sCD35 (CR1), sCD46 (MCP), sCD55/CD46 chimera, sCD59
- >> Inhibitory monoclonal antibodies to: mannose-binding lectin, properdin, factor B, factor D, C5a
- >> Monoclonal antibody to C5 (eculizumab) in clinical trials was effective in paroxysmal nocturnal hemoglobinuria
- >> Peptide inhibitors: C5aRa, C1q inhibitor
- >> Tissue-targeted inhibitors: CD59, CD35 targeted to tissue (L-selectin, CR2)

Phagocyte deficiencies

Gülbü Uzel, Steven M. Holland

21

We have learned a great deal about phagocytes since their discovery by Metchnikoff in 1905. Phagocytes (neutrophils, monocytes, macrophages and eosinophils) traffic to the site of infection or inflammation and engulf microorganisms and apoptotic cells as the lead players in the innate immune response. Within the last four decades, many defects of the phagocytic system have been described and molecular genetic lesions for many have been defined. Recently, promising steps have been taken towards correcting these immunologically disabling disorders. This chapter reviews disorders of phagocytes and how they affect the immune system.

■ PHAGOCYTE DIFFERENTIATION ■

Myeloid cell differentiation has been studied at many levels and a hierarchy of maturation steps has been established. The pluripotent stem cell, residing in the bone marrow or the circulation, is the precursor for all the elements of the hematopoietic system. Precursors eventually commit to a single lineage, which terminally results in functionally distinct cells. This complex process of lineage commitment is under strict regulation by stage-specific signals derived from cytokines and growth factors (Chapter 2) that interact with their cognate receptors on cells. In response to these regulatory factors, cells change size and nuclear shape while stage-specific organelles containing critical proteins for neutrophil phagocytosis, bactericidal activity and inflammatory properties are formed.

■ PRODUCTION OF MACROPHAGES AND GRANULOCYTES ■

The pluripotent stem cell gives rise to the myeloid stem cell, from which the colony-forming unit granulocyte-erythrocyte-macrophage-megakaryocyte (CFU-GEMM) is derived. Among the growth factors that are influential at this step are stem cell factor (SCF), interleukin-3 (IL-3), and granulocyte-macrophage colony-stimulating factor (GM-CSF). The CFU-GEMM further differentiates into the colony-forming

unit-granulocyte-macrophage (CFU-GM) under the continuing influence of these growth factors. The colony-forming unit-granulocyte (CFU-G), a neutrophil lineage committed precursor, is derived from CFU-GM under the control of IL-3, GM-CSF and granulocyte colony-stimulating factor (G-CSF). Further downstream in the myeloid maturation process the myeloblast is formed from the CFU-G under the influence of GM-CSF and G-CSF. This is the first morphologically distinct cell of the neutrophil lineage. Promyelocyte, myelocyte, metamyelocyte, band form and mature neutrophil formation follow consecutively under the ongoing control of G- and GM-CSF. The maturation process from stem cell to the myelocyte stage takes 4–6 days and an additional 5–7 days for the myelocyte to form the mature neutrophil. The half-life of neutrophils in the circulation is only 7 hours, but an astounding 10^{11} neutrophils are generated daily, a number that can be further expanded in the setting of infection. The circulating and marginated granulocyte pools comprise only a small percentage of the total granulocyte pool: 3% and 4%, respectively.

Macrophage differentiation is similar to granulocyte differentiation in many respects. The CFU-GM differentiates into the colony-forming unit-macrophage (CFU-M) followed by the formation of the monoblast, promonocyte and monocyte under the influence of macrophage colony-stimulating factor (M-CSF). After monocytes are released into blood, they circulate for 1–4 days before entering tissues, where they further differentiate into macrophages. Macrophages can be found in many tissues, including pleura, alveolae, peritoneum, liver (Küpfner cells), bone marrow, bone (osteoclasts), lymph nodes and the central nervous system (microglia). They are active participants in inflammation, granuloma formation, and the appearance of multinucleated giant cells.

■ EVOLUTION OF NEUTROPHIL GRANULES ■

During myelopoiesis in the bone marrow, the first granules form at about the promyelocyte stage, stain blue with a Wright or Romanowsky stain, and are called primary or azurophilic granules

(Chapter 2). Their formation ceases at the myelocyte stage and the formed primary granules are distributed among the daughter cells. These primary granules contain microbicidal enzymes, including defensins, hydrolases and proteases (Table 21.1). As the granulocyte precursors mature and divide, the number of primary granules per cell decreases. After the promyelocyte stage, secondary or specific granules form. In the mature neutrophil they comprise about two-thirds of the granules. The secondary granules are less dense and contain cytochrome b₅₅₈, lysozyme, lactoferrin, and collagenase. The third type of granule found in neutrophils, the gelatinase-containing tertiary granule, probably forms after the metamyelocyte stage and can be detected in the band form and mature granulocyte.

■ DISORDERS OF NEUTROPHIL PRODUCTION ■

Chronic neutropenia is the term used for conditions with absolute neutrophil counts (ANC) <500/μL lasting more than 6 months¹ Chronic neutropenia can have many etiologies, as listed in Table 21.2.

SEVERE CONGENITAL NEUTROPENIA (SCN) OR KOSTMANN SYNDROME

Although initially thought to have an autosomal recessive inheritance pattern, Kostmann syndrome has been recognized in sporadic cases and in families with autosomal dominant inheritance patterns as well. It is usually

Table 21.1 Neutrophil granule components

Granule	Contents	Properties
Primary (azurophilic) granules	<i>Lysosomal hydrolases</i> Myeloperoxidase Defensins Lysozyme Elastase Cathepsin G Azurocidin Proteinase 3 Bacterial – permeability increasing protein (BPI) <i>Acid hydrolases</i> Cathepsin B Cathepsin D β-Glycerophosphatase granulocyte β-Glucuronidase N-acetyl-β-glucosaminidase α-Mannosidase Other Collagenase	<ul style="list-style-type: none"> • First formed during myelopoiesis – at promyelocyte stage • Appear blue when stained with Wright's stain • Least mobilizable granule • Measure ~ 0.8 μm • Defensins constitute 30–50% of granule contents • Augment the microbial damage initiated by reactive oxidants • Help digest dead microbes and host cells • BPI neutralizes Gram-negative
Secondary (specific) granules	<i>Lysosomal hydrolases</i> Lysozyme <i>Other</i> Collagenase Gelatinase Lactoferrin Vitamin B ₁₂ binding proteins Cytochrome b ₅₅₈ Histaminidase FMLP receptors C3bi receptors	<ul style="list-style-type: none"> • Synthesis begins at the myelocyte stage • These granules are specific to phagocytes • Measure ~ 0.5 μm • Binding proteins deprive microorganisms of nutrients • Most are positively charged, enhancing cell surface
Tertiary (smaller) granules	<i>Acid hydrolases</i> Cathepsin B Cathepsin D β-Glycerophosphatase granulocyte β-Glucuronidase N-acetyl-β-glucosaminidase α-Mannosidase <i>Other</i> Gelatinase	<ul style="list-style-type: none"> • Heterogenous population of organelles including C-particles and secretory vesicles • Detected in the band form and mature

diagnosed in the neonatal period or early infancy as a result of life-threatening pyogenic infections, cellulitis, stomatitis, peritonitis, perirectal abscess or meningitis. The most common bacteria isolated are *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa*. Patients with this form of severe neutropenia usually have an ANC $<200/\mu\text{L}$, mild anemia and hypergammaglobulinemia. Eosinophilia and monocytosis may be detected.

SCN represents an impairment of myeloid differentiation due to maturational arrest of neutrophil precursors at the level of promyelocytes or myelocytes in the bone marrow. A subset of patients with SCN (7.5–10%) subsequently develops a myelodysplastic syndrome (MDS) or acute myeloid leukemia (AML). This has been associated with acquired truncation mutations of the G-CSF receptor (G-CSFR). Increased proliferative signaling by the truncated

G-CSFR has been associated with the development of acute myeloid leukemia and a loss of SRC-family kinase activation.² Heterozygous mutations in the gene encoding neutrophil elastase (*ELA2*) have also been reported in SCN. There is strong evidence for autosomal dominant inheritance of severe congenital neutropenia associated with *ELA2* mutation.³ These mutations lead to intracellular accumulation of mutant human neutrophil elastase protein in the cytoplasm and prevent its physiologic transport to azurophilic granules. Mutant neutrophil elastase protein may disturb intracellular trafficking and lead to neutrophil apoptosis. A recent survey of SCN patients who received long-term G-CSF revealed an increased rate of AML and MDS. The risk was parallel to the duration of G-CSF treatment and higher in patients who were less responsive to G-CSF.

Table 21.2 Causes of neutropenia

Classification	Etiology
Hematological	Kostmann syndrome Severe congenital neutropenia Cyclic neutropenia Myelodysplastic syndrome Aplastic anemia Leukemia
Immunological/inflammatory disorders	SCID Hyper-IgM syndrome Chediak–Higashi syndrome Cartilage–hair hypoplasia Reticular dysgenesis Dyskeratosis congenital Autoimmune neutropenia Isoimmune neutropenia
Infections	HIV Parvovirus Epstein–Barr virus Malaria Cytomegalovirus
Inborn errors of metabolism/nutritional disorders	Gaucher's disease Glycogen storage disease, type Ib Transcobalamin deficiency Vitamin B ₁₂ , folate deficiency
Other	Shwachman–Diamond syndrome Idiopathic neutropenia Chemotherapy Radiation therapy Drugs (e.g., vancomycin, chloramphenicol, sulfamethoxazole, clozapine) Toxins (e.g., benzene) Dialysis Reticuloendothelial sequestration

Treatment with daily subcutaneous G-CSF (1–120 µg/kg/day) results in an increase in ANC above 1000/µL, with a decrease in the frequency of infections and significant clinical improvement overall.

SHWACHMAN–DIAMOND SYNDROME (SDS)

Shwachman–Diamond syndrome was first described by Shwachman et al. in 1964 as a disorder with pancreatic exocrine insufficiency and bone marrow dysfunction.⁴ Today it is recognized as the second most common cause of inherited exocrine pancreatic insufficiency after cystic fibrosis. The estimated incidence of SDS is 0.5–1:100 000 live births. It is inherited as an autosomal recessive trait.

Disease-associated mutations were identified in the gene *SBDS*, located at 7q11.⁵ Recurring mutations were reported to result from gene conversion due to recombination with a pseudogene in 89% of unrelated patients; 60% carried two converted alleles. These gene conversion mutations in *SBDS* are common to different ethnic groups. The *SBDS* protein belongs to a highly conserved protein family involved in RNA metabolism. Mutations cause defects in the development of the exocrine pancreas, hematopoiesis and chondrogenesis.

Patients present with recurrent infections and failure to thrive in infancy. Features of SDS are hematopoietic dysfunction, metaphyseal dysostosis and growth retardation, and fatty replacement of the pancreas. Anemia and thrombocytopenia are associated with neutropenia. The majority of the patients have mild neutropenia, but a minority have neutrophil counts <500/µL. Neutropenia may be intermittent or persistent. Congenital aplastic anemia is an unusual presentation of SDS.⁶ Upper and lower respiratory tract pyogenic infections are the most common cause of morbidity and mortality and are related to neutropenia. An elevation in hemoglobin F is also reported in some cases. Leukemia has been observed in some SDS patients, although the exact frequency remains unknown.

Skeletal abnormalities are universal in patients with SDS. Short ribs with broadened anterior ends are the most common radiologic findings. Metaphyseal dyschondroplasia of the femoral head is frequent. Delayed bone age also may be a component of this multisystem disorder. The diagnosis can be made with the typical radiological findings, detection of abnormal pancreatic exocrine function (abnormal serum pancreatic α -amylase and total lipase activities, serum immunoreactive trypsinogen, fecal chymotrypsin and 3-day fat balance analysis) and serial hematologic evaluations. CT scans of the abdomen show typical fatty replacement of the pancreas.

Early replacement with pancreatic enzymes facilitates nutrition and growth. Subcutaneous administration of rG-CSF corrects neutropenia.

CYCLIC NEUTROPENIA

Human cyclic hematopoiesis or cyclic neutropenia (CN) is an autosomal dominant disease in which patients have approximately 21-day oscillations of blood-cell production. The neutrophils fluctuate between the lower limit of normal and zero. Platelets, monocytes and reticulocytes follow the same interval of oscillation but are out of phase with the neutrophils, hence the more appropriate title cyclic hematopoiesis. The frequency of this blood-cell disorder is estimated to be 0.5–1/1 000 000 population.

During the periods of neutropenia patients are prone to infections with pyogenic bacteria. The clinical presentation may be fever of unknown origin, gingivitis, stomatitis, oral ulcers, cellulitis, perirectal abscess, or more severe systemic pyogenic infections. Death from overwhelming infection is rare. Otherwise, it has a relatively benign course without

known predisposition to malignant disorders. Some patients may experience improvement in clinical symptoms, with the cycles being less noticeable as they grow older.

The genetic lesion has been mapped to chromosome 19p13.3 using genome-wide screening and positional cloning. Seven different single-base mutations in the gene encoding neutrophil elastase (*ELA2*) have been identified in affected families. The mutations are thought to lead to a gain of function in neutrophil elastase. Neutrophil elastase is synthesized during the promyelocyte and promonocyte stages and plays an important role in tissue destruction when released at the sites of inflammation. Various protease inhibitors, such as α_1 -antitrypsin, inhibit neutrophil elastase. The reason for the disordered cycling of hematopoiesis in CN is thought to be perturbed interaction between neutrophil elastase and its substrates, but the precise mechanism remains unknown.

CN should be suspected in the setting of recurrent infections at regular intervals and cyclic hematopoiesis. To be able to document these intervals and diagnose cyclic neutropenia, a full blood count with differential should be performed 2–3 times weekly for at least 6 weeks (through two cycles).

Treatment with subcutaneous rG-CSF improves the quality of life in affected patients by increasing the ANC during both the peaks and valleys of myelopoiesis. However, this treatment does not eliminate the cyclic oscillations of other blood elements. The subcutaneous dose of rG-CSF required for the maintenance of an ANC above 1000/µL in cyclic neutropenia is typically less than that required for the same effect in SCN.

AUTOIMMUNE NEUTROPENIA

Autoimmune neutropenia (AIN) is caused by peripheral destruction of neutrophils by granulocyte-specific autoantibodies present in a patient's serum.

Primary autoimmune neutropenia

Primary AIN is seen predominantly in infancy and is not associated with other systemic immune-mediated disorders such as systemic lupus erythematosus (SLE). It is the most common form of neutropenia seen in young children and affects both genders equally. In a recently published cohort of primary AIN the average age at diagnosis was 8 months. The majority of patients present with mild skin and upper respiratory tract infections. A small minority may suffer from severe infections such as pneumonia, meningitis or sepsis. The diagnosis of primary AIN may be coincidental, as some patients remain asymptomatic despite low neutrophil counts. Neutrophil counts usually vary between 0 and 1500/µL during the neutropenic phase, the majority of patients having a count >500/µL at the time of diagnosis. The ANC may transiently increase two- to threefold during a severe infection and return to neutropenic levels following resolution. Bone marrow examination is normal or shows increased cellularity. In some cases maturation arrest may occur, but myeloid precursors reach at least to the myelocyte/metamyelocyte stage. Phagocytosed granulocytes may be seen in the bone marrow, indicating that the removal of sensitized granulocytes begins there.

Detection of granulocyte-specific antibodies is the gold standard for diagnosing primary AIN. In some patients detection may require repeated testing. Direct granulocyte immunofluorescence testing (D-GIFT) is one of the most sensitive methods available for detection of anti-granulocyte antibodies.⁷ The vast majority of these are IgG; IgM antibodies are rare.

These antibodies are most commonly directed at the isolated glycoproteins of the granulocyte membrane and are designated neutrophil antigens (NA). These NA are located on the IgG receptor IIA or IIIB (FcγRIIA and FcγRIIb). In more than 70% of primary AIN, one of the NA isoforms is recognized specifically. The etiology of this disease remains unknown unless there is a clear association with parvovirus infection.

The prognosis of primary AIN is very good, as it is self-limited. Neutropenia usually disappears within 1–2 years. Disappearance of the autoantibodies from the circulation precedes normalization of neutrophil counts. Symptomatic treatment of infections with antibiotics is usually sufficient. Prophylactic antibiotic treatment should be reserved for those with recurrent infections. Cotrimoxazole, ampicillin, or first-generation oral cephalosporins are the most commonly used prophylactic antibiotics. Alternative treatment strategies for severe infections and in the setting of emergency surgical interventions include high-dose intravenous immunoglobulin (IVIG), corticosteroids, and rG-CSF, with the latter being the most effective at increasing the ANC.

Secondary autoimmune neutropenia

Secondary AIN can be seen at any age and has a more variable clinical course, in contrast to the early onset and relatively benign, short-lived course of primary AIN. Other systemic or autoimmune diseases, such as hepatitis, SLE or Hodgkin's disease, often accompany the neutropenia. Even if it is not evident at the time of diagnosis, patients are at risk for developing other autoimmune problems. The antineutrophil antibodies have pan-FcγRIII specificity and are not specific for the NA. CD18/CD11b antibodies have been detected in a subset of patients with secondary AIN. This neutropenia responds poorly to most therapies.

ALLOIMMUNE NEONATAL NEUTROPENIA (ANN)

ANN is caused by the transplacental transfer of maternal antibodies against the fetal neutrophil antigens NA1, NA2 and NB1,⁸ leading to immune destruction of neonatal neutrophils. These complement-activating antineutrophil IgG antibodies can be detected in about 1 in 500 live births. An NA-null phenotype in the mother with absence of expression of FcγRIII (CD16) has also been reported to be associated with immune neutropenia in the neonate. Antibody-coated neutrophils in ANN are phagocytosed in the reticuloendothelial system and removed from the circulation, leaving the neutropenic neonate at risk for infections. Omphalitis, cellulitis and pneumonia presenting within the first 2 weeks of life in the setting of neutropenia form the clinical picture. The diagnosis can be made by detection of neutrophil-specific alloantibodies in the maternal serum. ANN responds to G-CSF or high-dose IVIG, but most patients improve without specific treatment in a few weeks to 6 months.

DEFECTS OF LEUKOCYTE ADHESION

Migration of circulating leukocytes from the bloodstream into the tissues depends on complex bidirectional interactions between leukocytes and endothelial cells. The initial steps involve the activation of circulating leukocytes by inflammatory signals released from inflamed

tissues or by bacteria. After activation by chemotactic factors such as the complement fragment C5a, IL-8, leukotriene B₄ (LTB₄) or the bacterial product formyl-methionyl-leucyl-phenylalanine (fMLP), leukocytes rapidly become adhesive to the endothelium, other leukocytes, or laboratory surfaces. The activation process involves translocation of subcellular granules containing adhesion molecules (CD18/CD11b) to the surface of polymorphonuclear leukocytes (PMN), and qualitative alterations in the adhesion molecules constitutively expressed on the plasma membrane. Endothelial cells are similarly activated, resulting in enhanced expression of adhesion molecules. Adhesion and transmigration of leukocytes occur as a result of interactions between three groups of molecules: leukocyte integrins, endothelial intercellular adhesion molecules (ICAMs, members of the immunoglobulin supergene family), and glycosaminoglycans or selectins (Fig. 21.1).⁹ The first step in targeting PMNs to inflamed tissues is the rolling or tethering of PMNs on the endothelium of postcapillary venules. This is due to the interactions between CD15s (sialyl Lewis^x or SLe^x) expressed on the leukocyte surface and P-selectin or E-selectin – members of the selectin family of adhesion molecules – expressed on the vascular endothelium. In addition, L-selectin on the leukocyte surface interacts with its counter-ligands P-selectin, CD34, glyCAM-1 and other glycoproteins located on the endothelial surface. Rolling, a relatively low-affinity interaction

Fig. 21.1 Leukocyte adhesion to nonlymphoid endothelium. *Selectins* (L-selectin/CD62L, P-selectin/CD62P and E-selectin/CD62E), *integrins* (CD18/CD11a or LFA-1, CD18/CD11b or Mac-1 and CD18/CD11c or p150,95) and *intercellular adhesion molecules* (ICAMs) are involved in leukocyte adhesion to the nonlymphoid endothelium. Rolling, the initial step of leukocyte adhesion, is mediated by the interactions of E-selectin and P-selectin on endothelial surfaces with the sialyl Lewis^x (SLe^x or CD15s) of leukocytes as well as L-selectin on the leukocyte surfaces with its counter-ligands CD34 or glyCAM-1. This low-affinity tethering or rolling facilitates tight adhesion as a result of the interactions of LFA-1 with ICAM-1 or ICAM-2 and Mac-1 with ICAM-2. CD18 is the molecule that is missing or dysfunctional in LAD I, SLe^x is the missing molecule in LAD II.

mediated by selectins, is followed by firm adhesion (in the setting of neutrophil activation), which is a high-affinity interaction between integrins on the neutrophil and ICAMs on the endothelium. Adhesion is followed by the transmigration of neutrophils between endothelial cells out to the extracellular matrix. Activated, extravasated leukocytes interact with extracellular matrix proteins and pathogens, resulting in the release of proteolytic enzymes and toxic oxygen radicals.

There are two well-characterized immunodeficiencies related to defects in leukocyte adhesion.

LEUKOCYTE ADHESION DEFICIENCY I (LAD I)

The first reports of this disorder appeared in the medical literature in the 1970s. Infants and children were recognized with severe, recurrent life-threatening bacterial infections affecting the skin, gingiva, gut and lung.¹⁰ A common feature in some of these patients was delayed separation of the umbilical stump and severe omphalitis. These patients were shown to have defects in membrane expression of the leukocyte adhesion glycoproteins of the integrin superfamily.

Integrins are cell surface receptors of noncovalently associated heterodimeric chains, comprised of one α subunit (either CD11a, CD11b or CD11c) and a common β chain (CD18) that is required for surface expression of the CD11 chains. These proteins mediate leukocyte adhesion to the endothelium and other leukocytes in the case of CD18/CD11a (LFA-1), to iC3b in the case of CD18/CD11b (Mac-1 or CR3), and to endothelium in the case of CD18/CD11c (CR4 or p150,95). These molecules are expressed differentially on different classes of leukocyte. LAD I results from mutations in the gene encoding the common β chain CD18, located on chromosome 21q22.3. The mutations described in CD18 are heterogeneous.

Patients with LAD I show the expected defective polymorphonuclear functions. Impaired adherence leads to defective chemotaxis and adherence, and low natural killer (NK) and cytotoxic T lymphocyte (CTL) activity. The absence of CR3 leads to loss of complement-mediated phagocytosis and bacterial killing. There is evidence for increased intravascular granulocyte survival time in these patients.

LAD I is divided into the broad phenotypes of severe and moderate. In the severe form (<0.5% of CD18 expression) death from infection often occurs before age 2 in the absence of bone marrow transplantation. The severe form is often manifested by delayed umbilical cord separation, omphalitis, persistent leukocytosis, destructive periodontitis and recurrent infections with *Staphylococcus aureus*, *Pseudomonas aeruginosa* and *Klebsiella* sp.¹¹ In the moderate phenotype (>1% of normal CD18 expression), patients live beyond childhood with less frequent or severe infections than severely affected patients, and do not typically have delayed umbilical cord separation. Patients with the moderate phenotype are usually diagnosed later in life but show similar abnormalities at the cellular level. Persistent neutrophil leukocytosis (usually >15 000/ μ L) in the absence of infection is common in the moderate and severe forms.¹¹ Oral ulcers, severe periodontitis, gingivitis with apical bone loss (Fig. 21.2), and eventual loss of permanent teeth are major problems in LAD I.

Necrotizing cutaneous ulcers with delayed wound healing and lingering eschar formation are common (Fig. 21.3). Defective chemotaxis and adhesion means that leukocytes fail to migrate to sites of infection, accounting for the inability to form pus and erythema at the site of infection. Biopsies of the ulcers show poorly formed granulation tissue and

Fig. 21.2 Oral pathology in a patient with leukocyte adhesion deficiency type I (LAD I). Gingivitis and severe periodontitis are hallmarks of LAD I.

Fig. 21.3 Skin infection of a patient with leukocyte adhesion deficiency type I (LAD I). Failure to form pus, inability to demarcate the fibrotic skin debris, and limited inflammation. *Enterococcus gallinarum* was cultured from the wound.

scant fibrinous exudate without neutrophils. Ulcerative gastrointestinal disorders resembling idiopathic inflammatory bowel disease are also recognized in this immunodeficiency.

MUTATIONS IN LAD I

Dysfunctional and nonfunctional mutations in the gene encoding CD18 give rise to LAD I. Although most cases are from consanguineous unions, there have been several reports of compound heterozygotes with the moderate phenotype. Mutations may be grouped into five categories, similar to the type of mutation seen in chronic granulomatous disease (CGD): promoter defects, missense mutations, nonsense mutations, deletions and splice site mutations.¹²

KEY CONCEPTS

LEUKOCYTE ADHESION DEFICIENCY

- >> Two types of adhesion defect are known: LAD I and LAD II. There are two phenotypes for LAD I: moderate and severe.
- >> LAD I results from an absence of CD18, whereas in LAD II sialyl Lewis^x (CD15s) is defective.
- >> High white cell count, delayed umbilical cord separation, recurrent bacterial infections, skin ulcers, defective wound healing, gingivitis and periodontitis are the hallmarks of LAD I.

DIAGNOSIS OF LAD I

A diagnosis of LAD I is suggested by a history of delayed umbilical cord separation; persistent leukocytosis; septicemia; recurrent bacterial infections of the skin, lungs, upper airways, perirectal area and bowels; failure to develop an inflammatory response; necrotizing skin ulcers with poor healing; eschar formation; severe gingivitis; and periodontal disease with tooth loss. A definitive diagnosis can be made with flow-cytometric analysis of patient leukocytes showing decreased or absent CD18 and its associated heterodimers: CD11a, CD11b and CD11c. Parents of the proband, who must be heterozygous carriers, usually have 50–60% of normal expression of these receptors.

MANAGEMENT OF LAD I

Definitive therapy of LAD I is bone marrow transplantation, especially in the severe phenotype. Bone marrow engraftment in LAD I is more successful than in other immunodeficiencies, as absent or deficient LFA-1 on leukocytes leads to defective CTL function. Infections must be managed aggressively, as the inflammatory responses and clinical signs are unreliable. Surgery is often essential for debridement of non-healing ulcers, which frequently need tissue grafts. Gene therapy may be a treatment alternative in the future in those for whom transplant is not an option. *In vitro* gene therapy has successfully restored CD18 on B cells and peripheral blood leukocytes.¹³ Cytokines that can regulate the expression of adhesion proteins may someday be of value.

LEUKOCYTE ADHESION DEFICIENCY II (LAD II)

The LAD II phenotype was not confined to hematopoietic cells: patients suffered from growth and mental retardation, hypotonia, seizures, dysmorphic features, strabismus, and persistent periodontitis. Leukocytosis in the absence of infection was a striking clinical finding. In contrast to LAD I, wound healing is not impaired, nor is the susceptibility to bacterial infections as severe as in LAD I.

Hypofucosylation of the glycoconjugates that form the critical structural elements of CD15s (sialyl Lewis^x, SLe^x) on neutrophils leads to abnormal ligand. SLe^x is the ligand for the selectin family of adhesion proteins and functions in the rolling step of neutrophil

adhesion. Therefore, defects in SLe^x adhesion cause abnormal rolling of neutrophils along the endothelium. The underlying defect is due to a generalized defect in *de novo* GDP-fucose biosynthesis. The mutation is in GDP-fucose transporter-1. In addition to severe impairment in neutrophil migration to the skin similar to that of LAD I, lymphocyte homing to the skin is also defective in LAD II. Patients with LAD II may have mild courses of infections, with several pneumonias and superinfection of varicella lesions. In addition to SLe^x, other fucosylated blood group antigens are also affected, leading to the Bombay blood group phenotype (lack of the H antigen) and Lewis a[−]b[−] in these patients. Absence of CD15s on patient neutrophils is shown by flow cytometry.

Effective and prompt treatment of infections is central to the management of LAD II. Oral fucose supplementation in one patient with LAD II was reported to induce clinical and laboratory improvement. However, this has not been observed in all cases.¹⁴

CHRONIC GRANULOMATOUS DISEASE (CGD)

Chronic granulomatous disease (CGD) was first described in the 1950s as a disorder of phagocytic cells leading to recurrent infections. Today it is known that CGD comprises a group of four inherited disorders with a common phenotype (Table 21.3), characterized by recurrent severe bacterial and fungal infections and tissue granuloma formation.¹⁵ CGD occurs with a frequency of 0.5–1/100 000 as a result of deficient superoxide (O₂[−]) generation via the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase system. It is inherited in X-linked and autosomal recessive patterns. Common clinical problems are related to recurrent infections with catalase-positive bacteria and fungi. Patients with CGD often present with pneumonia, liver abscess, skin infections, lymphadenitis or osteomyelitis; bacteremia is relatively uncommon. The formation of exuberant tissue granulomas at sites of infection, at surgical wounds and in hollow viscera is a frequent problem seen more often in patients with the X-linked form of CGD.

NADPH OXIDASE AND ITS ACTIVITY

The NADPH oxidase transfers an electron to molecular oxygen by way of flavin adenine dinucleotide (FAD) and heme to form O₂[−]. This multicomponent system contains two structural elements (Fig. 21.4). Cytochrome b₅₅₈ is a membrane-bound heterodimer lodged in the wall of the secondary granules which on activation fuses with the wall of the phagolysosome or plasma membrane. The large glycosylated β subunit is gp91^{phox} (phagocyte oxidase) and the small nonglycosylated α subunit is p22^{phox}. These proteins are anchored to the plasma membrane by multiple transmembrane domains. Cytochrome b₅₅₈ binds FAD and two heme groups, which mediate the final steps of electron transfer to O₂. However, both of these subunits are required for the flavocytochrome. The cytoplasmic tail of gp91^{phox} includes the NADPH- and FAD-binding sites. Oxidase activity is initiated by many factors, for example the binding of chemotactic molecules such as *N*-formylmethionyl oligopeptides (e.g., fMetLeuPhe) to their receptors on the neutrophil surface. This leads to the formation of the cytosolic NADPH oxidase activation complex, comprised of four

Table 21.3 Notation used to describe different phenotypes of X-linked CGD

Fig. 21.4 Schematic representation of the NADPH oxidase system. Chemoattractants interact with their receptors on the neutrophil surface, leading to an increase in intracellular calcium concentration. This activation results in the assembly of the NADPH oxidase complex following phosphorylation of cytosolic factors. This in turn leads to superoxide production. DAG, diacylglycerol; PIP₂, phosphatidylinositol bisphosphate; IP₃, inositol triphosphate; α, β, γ, subunits of the GTP-coupled receptors.

proteins, p47^{phox}, p67^{phox}, p40^{phox} and the small GTP binding proteins p21^{rac1}/p21^{rac2}. p47^{phox}, p67^{phox} and p40^{phox} bind to one another via interaction of SH3 domains and proline-rich regions. This trimolecular complex docks with the cytochrome at the membrane via association of the phosphorylated p47^{phox} and the proline-rich region of the carboxy-terminus of p22^{phox}. The interaction between p67^{phox} and the α helix overlying the nucleotide-binding domain of NADPH is also important. p21^{rac}, the small GTP-binding protein of the NADPH oxidase activation complex, is involved in the regulation of oxidase activity. When stimulated, p21^{rac} dissociates from the GDI-dissociation inhibitor protein GDI and binds to p67^{phox} in the activation complex, leading to the translocation of the p67^{phox} complex to the membrane. Activation of the complex results in phosphorylation of p47^{phox} as well as p67^{phox}, gp91^{phox}, and p22^{phox}.

MUTATIONS LEADING TO CGD

X-linked CGD

The most common form of CGD is caused by mutations in the gene encoding gp91^{phox} (CYBB) at Xp21.1 (Table 21.3). The largest series studied to date, of 131 kindreds, found large and small deletions (11%), frame shifts (24%), nonsense mutations (23%), missense mutations (23%), splice region mutations (17%), and regulatory region mutations (2%).¹⁶ Carrier detection revealed a functionally abnormal phagocyte population in 89% of mothers, making for a spontaneous mutation rate of approximately 11%. In several patients with large interstitial deletions, adjacent genes are affected, causing McLeod syndrome, Duchenne muscular dystrophy, or X-linked retinitis pigmentosa in addition to

CGD. The clinical phenotype of McLeod syndrome includes compensated hemolysis, acanthosis, and progressive neurodegenerative symptoms such as areflexia, dystonia and choreiform movements. McLeod syndrome is characterized by absent erythrocyte Kx protein and diminished levels of Kell blood group antigens. These patients may form anti-Kx and anti-Km antibodies when transfused, making future transfusions extremely difficult. Therefore, all X-linked CGD patients should be carefully screened for Kell blood groups.

Autosomal recessive CGD

Mutations in the genes encoding the NADPH oxidase components p47^{phox}, p67^{phox} and p22^{phox} cause autosomal recessive forms of CGD, accounting for approximately 35% of all cases. Mutations in the gene encoding p22^{phox} (*CYBA*), located at 16q24, are responsible for 6% of all CGD cases. Mutations in the gene for p67^{phox} (*NCF2*, located at 1q25) and p47^{phox} (*NCF1*, located at 7q11.23) cause respectively <5% and 25% of all CGD mutations. The great majority of patients with p47^{phox} deficiency are homozygous for a GT deletion at the start of exon 2.¹⁷ A few patients have been reported who are heterozygous for the GT deletion, with the second allele carrying a G deletion at position 502. p67^{phox} and p22^{phox} deficiencies are caused by deletions, insertions, missense and splice site mutations. All these genetic lesions lead to either the absence or the diminished production of the affected protein. Some CGD patients have normal amounts of nonfunctional protein due to missense mutations. So far no autosomal dominant cases have been confirmed.

CLINICAL MANIFESTATIONS OF CGD

The first severe infection is usually in infancy or childhood, although adults have been diagnosed with CGD as well. Late diagnoses usually occur in patients with some residual superoxide production. Patients with the p47^{phox}-deficient genotype have a better prognosis and a less severe clinical phenotype overall.

The keys to diagnosis are severe infections with catalase-positive pathogens in an otherwise healthy host. Recurrent pyogenic infections with *Staphylococcus aureus*, *Burkholderia cepacia*, *B. gladioli*, *Serratia marcescens*, *Chromobacterium violaceum*, *Aspergillus* sp. and *Nocardia* sp. are highly suggestive of CGD, whereas streptococcal infections are not. Infections may be widely disseminated and fatal, but are most commonly pneumonia, lymphadenitis, liver abscess, skin abscess, perianal abscess, and osteomyelitis. As in other neutrophil defects, the most common pathogen is *S. aureus*. Staphylococcal liver abscesses, which are dense and caseous, are common in CGD and cause significant morbidity. Their fibrocaseous consistency means that percutaneous drainage is rarely successful and open surgery is required. Invasive pulmonary aspergillosis is the primary cause of death in North American CGD. *A. fumigatus* and *A. flavus* are commonly isolated, but *A. niger* and *A. nidulans*, species with low pathogenicity in the normal host, have been frequently reported in CGD. *Aspergillus* pneumonia is usually detected via computed tomography (CT) as a well-circumscribed consolidation in the peripheral lung parenchyma (Fig. 21.5). Thoracic wall invasion may occur, leading to osteomyelitis of the ribs, perforation of the diaphragm, or cutaneous abscesses. In this setting surgical resection of the infected tissue is often required, in addition to treatment with specific antifungal antibiotics. *Aspergillus* infections in CGD are often unaccompanied by systemic symptoms or signs of infection (e.g. fever,

Fig. 21.5 CT scan of the lungs of a patient with chronic granulomatous disease (CGD) and *Aspergillus* pneumonia. *Aspergillus* pneumonia is detected as a peripheral consolidation in the lung parenchyma.

leukocytosis) and should therefore be suspected in any case of an asymptomatic pulmonary infiltrate. *Aspergillus nidulans* is especially likely to invade bone and be complicated. Septicemia is uncommon, but can occur with *B. cepacia*, often associated with pneumonia, *C. violaceum* following skin inoculation in brackish waters, or *S. aureus* in the setting of osteomyelitis.

Recently, a novel Gram-negative rod was identified from necrotic lymph nodes in several patients with CGD.¹⁸ It was identified as a member of the family Acetobacteraceae and named *Granulobacter bethesdensis*.

Inflammatory granuloma formation is one of the hallmarks of CGD. The association with infection is not clear. Pyloric outlet obstruction, bladder outlet obstruction and ureteral obstruction are commonly encountered problems due to granuloma formation. A Crohn's-like inflammatory bowel disease is part of this inflammatory spectrum and may involve the esophagus (Fig. 21.6), jejunum, ileum, cecum, rectum and perirectal area in over 40% of X-linked patients. Gastrointestinal manifestations include diarrhea and malabsorption. Lipid-laden pigmented histiocytes are often seen in biopsies. GI involvement is common in CGD patients, with abdominal pain, growth delay, or hypoalbuminemia. In a large series of CGD patients evaluated for GI involvement, 43% of X-linked CGD patients and 11% of p47-deficient CGD patients had inflammatory bowel disease. The median age of initial GI manifestations was 5 years. Abdominal pain was the most frequent symptom (100%), and hypoalbuminemia was the most frequent sign (70%). GI involvement had no effect on mortality and was unaffected by the use of IFN- γ .¹⁹

Granulomata respond very well to steroids with a slow taper over several weeks to months. Exuberant formation of granulation tissue and dysregulated cutaneous inflammatory responses lead to wound dehiscence and impaired wound healing in CGD (Fig. 21.7). Autoimmune or rheumatologic problems, such as discoid lupus erythematosus, systemic lupus erythematosus and polyarthritis resembling juvenile rheumatoid arthritis, have been reported at higher than normal levels in CGD.

Polymorphisms in Fcγ receptors and myeloperoxidase, key molecules in host defense, have been linked to an increased risk of developing gastrointestinal or autoimmune and rheumatologic complications in CGD.

DIAGNOSIS OF CGD

In the setting of severe, recurrent infections with catalase-positive organisms involving the lung, liver or granuloma formation in the gastrointestinal or genitourinary tract, a diagnosis of CGD should be considered. The diagnosis is established by the inability of neutrophils to reduce nitroblue tetrazolium dye (Fig. 21.8), to produce chemiluminescence, or to oxidize dihydrorhodamine on appropriate stimulation. The dihydrorhodamine (DHR) assay is the most sensitive and enables quantification of the oxidative capacity of neutrophils. This flow-cytometric assay of oxidative burst can also help suggest the genotype of CGD involved.²⁰

Fig. 21.6 Esophageal involvement in chronic granulomatous disease (CGD). Esophageal strictures caused by granuloma formation as seen on barium swallow.

TREATMENT OF CGD

Prophylactic trimethoprim-sulfamethoxazole (TMP-SMX) significantly reduces the frequency of bacterial infections in CGD, especially those caused by *S. aureus*. TMP-SMX prophylaxis is ineffective against fungal infections but does not encourage them. Prophylactic itraconazole prevents fungal infections, as proven prospectively.²¹ Leukocyte transfusions are sometimes used during severe infections in addition to antibiotics, although the benefits are unproven. Bone marrow transplants can cure CGD even in the setting of active infection. However, transplant-related morbidity and mortality remains a significant problem.

IFN-γ is beneficial as a prophylactic treatment in CGD. In a multicenter placebo-controlled trial of IFN-γ the number and severity of infections were significantly reduced in the IFN-γ arm.²² The exact

Fig. 21.7 Exuberant granuloma formation in chronic granulomatous disease (CGD). Wound dehiscence and impaired wound healing at surgical incision sites due to dysregulated inflammatory responses in an X-linked CGD patient.

CLINICAL PEARLS

CHRONIC GRANULOMATOUS DISEASE (CGD)

- >> CGD comprises a group of four inherited disorders with a common phenotype.
- >> Infections with catalase-positive bacteria and fungi, and granuloma formation in the gastrointestinal and urinary tract are the major problems in CGD.
- >> Oral prophylactic antibiotics and subcutaneous IFN- γ injections three times a week are currently recommended for CGD.
- >> Diagnosis can be made via NBT test or DHR assay, the latter being a more sensitive diagnostic tool.

mechanism of action of IFN- γ is not known, but it has a multifaceted effect, probably including stimulation of components of NADPH oxidase in partial deficiencies, increased bactericidal activity through neutrophil granule components, and Fc receptor expression. Increased nitric oxide production in CGD neutrophils with IFN- γ treatment suggests an alternative mechanism in augmenting host defense. Subcutaneous administration of recombinant IFN- γ three times a week at a dose of 50 $\mu\text{g}/\text{m}^2$ (for those with body surface area $>0.5 \text{ m}^2$) is recommended. The adverse effects of recombinant IFN- γ in patients with CGD have been limited to fever, chills, headache, flu-like illness and diarrhea.

Gene therapy aims to provide CGD patients with genetically corrected autologous progenitor stem cells. Retrovirus-mediated gene transfer has been successful in p47^{phox} and gp91^{phox} knockout mouse models. Oxidase-positive granulocytes in patients with p47^{phox}-deficient CGD have been achieved transiently via gene therapy. Recently, two adults received gene therapy after nonmyeloablative bone marrow conditioning.²³ In these patients, gene transfer led to functionally corrected phagocytes and clinical improvement.

Fig. 21.8 Laboratory diagnosis of chronic granulomatous disease (CGD) with the nitroblue tetrazolium test (NBT). **(A)** NBT reduction by purified normal neutrophils following stimulation with phorbol esters and calcium ionophore. NBT is reduced by all neutrophils, showing a blue/purple deposit. **(B)** NBT reduction by purified neutrophils from an X-linked CGD carrier; two different populations of cells are seen. Normal (unaffected cells) reduce the NBT dye and stain blue/purple, whereas affected cells fail to reduce the NBT dye and appear clear. **(C)** Neutrophils from a patient with CGD fail to reduce the NBT dye and appear clear. (Courtesy of Dr Douglas B. Kuhns, SAIC, Frederick, MD.)

■ HEREDITARY MYELOPEROXIDASE DEFICIENCY ■

Hereditary myeloperoxidase deficiency (MPO) is characterized by a lack of myeloperoxidase activity. Myeloperoxidase is a heme-containing enzyme necessary for the conversion of H_2O_2 to $HOCl$ and the subsequent killing of phagocytosed bacteria, fungi and viruses. MPO is expressed early in myeloid differentiation and resides in the azurophilic granules of neutrophils and the lysosomes of monocytes. The resulting mature protein is a symmetric molecule of four peptides, with each half consisting of a heavy-light chain heterodimer.

Neutrophils of MPO-deficient individuals fail to produce $HOCl$ upon stimulation, but the NADPH oxidase system remains unaffected. Prolonged and higher levels of superoxide and H_2O_2 production following stimulation have been observed in MPO-deficient neutrophils. This is thought to be due to the lack of negative feedback regulation of $HOCl$ on the NADPH oxidase, although the exact mechanism for this is unknown. MPO deficiency can be seen in two forms: primary (congenital) and secondary (acquired).

PRIMARY MPO DEFICIENCY

The primary form of MPO deficiency is the most common phagocyte defect, with a frequency of 1:4000, and is caused by germline mutations. There is heterogeneity among patients in the degree of MPO deficiency: both total and partial deficiencies have been described. Patients with primary MPO deficiency do not usually have an increased incidence of infections, probably because MPO-independent mechanisms compensate for the lack of MPO-dependent microbicidal activity. Most individuals have been diagnosed incidentally when MPO activity was used for specific neutrophil staining, for example in some automated differential readers. In some patients visceral candidiasis has occurred in the setting of concurrent diabetes. However, the frequency of such cases is very low. Affected patients may develop nonfungal infections, malignancies and certain skin disorders. In several cohorts of complete MPO-deficient patients an increased incidence of solid or hematologic tumors has been observed. Neutrophils have no apparent defect in phagocytosis of bacteria or fungi. However, microbicidal activity is slower than normal. These MPO-deficient neutrophils are unable to kill *Candida* or *Aspergillus* by *in vitro* assays, but patients do not develop *Aspergillus* infections. The association of malignancy and MPO deficiency remains uncertain, but may be related to the depressed cytotoxic activity against tumor cells.

The most common mutation is a missense change resulting in the replacement of arginine at position 569 with tryptophan (R569W). This causes a maturational arrest of the MPO precursor and prevents heme incorporation. Most patients are compound heterozygotes. The diagnosis of MPO deficiency can be made using anti-MPO monoclonal antibodies for flow-cytometric analysis of the neutrophil population. No MPO expression is seen in the congenital deficiency, whereas near-normal antigenic reactivity is seen with the acquired form.

Maintenance antibiotic or antifungal therapy is not routinely recommended. In patients with diabetes mellitus and congenital MPO deficiency, who may develop localized or systemic infections, prompt and prolonged therapy is advised.

SECONDARY OR ACQUIRED MPO DEFICIENCY

In the majority of patients MPO deficiency is partial and transient. Secondary MPO deficiency occurs under certain clinical conditions, such as some hematologic malignancies or disseminated cancers, exposure to cytotoxic agents or anti-inflammatory medications, iron deficiency, lead intoxication, thrombotic diseases, renal transplants and pregnancy. MPO activity in the bone marrow myeloid precursors as well as peripheral blood cells shows variation from cell to cell. Treatment of the underlying condition typically corrects the defect. This deficiency is most likely linked to somatic mutations in the case of malignancy or toxic-metabolic effects on MPO activity.

SPECIFIC GRANULE DEFICIENCY

Neutrophil-specific granule deficiency (SGD) is a rare disorder of leukocyte maturation in which neutrophil secondary granules are absent. SGD is characterized by frequent, severe bacterial infections. The several patients reported shared the common features of frequent, severe pyogenic infections, a paucity or absence of neutrophil-specific granule proteins and defensins, and atypical neutrophil nuclear structure with mostly bilobed nuclei. *In vitro*, these patients' cells showed diminished neutrophil migration, reduced staphylococcal killing, reduced phagocytosis and an increased cell surface/volume ratio. Eosinophils and platelets are also affected in SGD. Platelets lack high molecular weight von Willebrand factor multimers, and have reduced platelet fibrinogen and fibronectin due to diminished platelet α granules. Bleeding diatheses and neutrophil phagocytosis of platelets are seen in SGD. In addition, SGD eosinophils are deficient in the eosinophil-specific granule proteins eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN) and major basic protein (MBP), despite the presence of mRNA transcripts for these proteins. Early reports of normal levels of lactoferrin in saliva and mucus, but absent lactoferrin in neutrophils, indicated that the lactoferrin deficiency in SGD was tissue specific and therefore probably involved myeloid-specific transcriptional regulation. The knockout mouse model for the CCAAT/enhancer binding protein (C/EBP) ϵ , a member of the leucine zipper family of transcription factors expressed in myeloid cells, showed absent secondary and tertiary neutrophil-specific granule proteins, bilobed nuclei, defective chemotaxis, and a predilection to infections early in life. Based on the close similarity between the C/EBP ϵ KO mouse and SGD, the C/EBP ϵ locus has been identified in an SGD patient as having a 5 bp deletion leading to a frameshift and a loss of transcriptional activity of C/EBP ϵ . This homozygous defect resulted in a promyelocyte-myelocyte transition block, absence of secondary granules and proteins, and a selective loss of the primary granule defensins, which are important elements in oxygen-independent microbicidal host defense. Few patients have been reported to have survived beyond adolescence. Bone marrow transplantation should be considered early in the disease.

■ CHEDIAK-HIGASHI SYNDROME ■

Chediak-Higashi syndrome (CHS) is a rare, autosomal recessive disorder characterized by partial oculocutaneous albinism, increased susceptibility to infections, deficient NK cell activity, and abnormal giant

KEY CONCEPTS

SPECIFIC GRANULE DEFICIENCY (SGD)

- >> SGD is caused by promyelocyte–myelocyte transition block due to a mutation in the *C/EBP ϵ* gene.
- >> Absence of secondary granule proteins, and a selective loss of the primary granule defensins are the pathologic findings in SGD granulocytes.
- >> The prognosis is very poor in SGD.

primary granules in neutrophils. This immunodeficiency was first reported by Beguez-Cesar in 1943 and then further described by Chediak and Higashi a decade later. The hallmark of CHS is giant abnormal granules in all granule-containing cells, including melanocytes (melanosomes are members of the lysosomal lineage of organelles), neutrophils, central and peripheral nerve tissue, fibroblasts and hair. The problem is the inability to form appropriate lysosomes and cytoplasmic granules. Compared to specific granule deficiency, CHS granulocytes lack cathepsin G and elastase. On the other hand, SGD PMNs are almost completely deficient in defensins, whereas the defensin content in CHS PMNs is normal. These findings indicate that the giant granules of CHS are derived predominantly from the azurophilic granules.

CHS is classically described as a biphasic immunodeficiency, in which susceptibility to infection marks the first phase and an accelerated lymphoproliferative syndrome with histiocytic infiltration of various tissues marks the second. Disorders similar to CHS occur in many species. Rarely, the accelerated phase may be the initial presentation.²⁴ The giant organelles are derived from the late compartments of the endocytic pathway, affecting specifically late endosomes and lysosomes and having minimal or no effect on early endosomes. The *beige* mouse is an animal model of CHS that helped locate the *chs1* gene to chromosome 13 in the mouse and pointed out the homologous region 1q43 in humans. *CHS1* encodes a 3801 amino acid peptide (*Lyst*, lysosomal transporter) that has a vital role in lysosomal trafficking. Lysosomal exocytosis triggered by membrane wounding is impaired in both human Chediak–Higashi and beige mouse fibroblasts.²⁵ The reduced survival of fibroblasts after wounding indicates that impaired lysosomal exocytosis inhibits membrane resealing. Lysosomal exocytosis was increased when the normal lysosomes were restored by expression of the *LYST* protein. Inability of cells to repair plasma membrane lesions may contribute to the pathology of CHS. The exact mechanism by which *LYST* regulates lysosomal functions is yet to be identified.

The dermatologic manifestations of CHS are striking. The degree of albinism may vary from a slightly diluted skin pigment to hypopigmented skin and hair, photophobia, nystagmus, strabismus, macular hypoplasia and reduced visual acuity. Skin biopsies show large irregular melanin granules in melanocytes. Microscopic analysis of hair also shows poor distribution of melanin. Pancytopenia, neutropenia and lack of NK-cell activity result in frequent pyogenic infections, usually due to staphylococci or streptococci. Hepatosplenomegaly and lymphadenopathy are common. A mild bleeding diathesis is due to platelet storage pool deficiency. Neurologic dysfunction has been noted in CHS, including mental retardation, seizures, cranial nerve palsies and progressive peripheral neuropathy.

The lymphoma-like lymphohistiocytic accelerated phase is characterized by increased hepatosplenomegaly, lymphadenopathy and worsened pancytopenia, which may resemble the virus-associated hemophagocytic syndromes or familial erythrophagocytic lymphohistiocytosis. Although chemotherapy can induce transient remissions, relapses are common. HLA-identical bone marrow transplantation has been successful in prevention of the accelerated phase and restoration of NK-cell function, but it does not resolve the central or peripheral nervous abnormalities.

Demonstration of giant azurophilic cytoplasmic inclusions on peripheral blood smears in the setting of the clinical findings provides a diagnosis of CHS; mutation analysis can confirm the diagnosis.

■ HYPER-IGE RECURRENT INFECTION (HIES OR JOB) SYNDROME ■

HIES is now recognized to be a multisystem autosomal dominant disorder characterized by recurrent infections of the lower respiratory system and skin, chronic eczema, extremely elevated IgE levels and eosinophilia (Table 21.4). HIES occurs in all racial and ethnic groups.

FACIAL, SKELETAL AND DENTAL ABNORMALITIES

Facial abnormalities seen in the majority of patients are a protruding, prominent mandible and forehead, apparent ocular hypertelorism, a broad nasal bridge and a wide, fleshy nasal tip with increased interalar distance (Fig. 21.9). Midline anomalies common in this disorder are a high-arched palate and midline sagittal clefts of the tongue. A single patient with HIES was reported to have a cleft lip and palate.

Skeletal abnormalities are common in this disorder, with a high incidence of fractures (57%) and scoliosis (76%) (Fig. 21.10). In addition, low bone density and cortical bone loss have been observed. Other infrequent skeletal abnormalities reported in HIES are craniosynostosis, spina bifida, bifid rib, wedge-shaped lumbar vertebrae, hemivertebrae and pseudoarthritis of the hip. Hyperextensibility of joints is common. A unique dental abnormality seen in this syndrome is retained primary teeth causing delayed eruption of the permanent teeth. This may be due to reduced resorption of primary tooth roots.

INFECTIONS AND IMMUNOLOGIC CHARACTERISTICS

Moderate to severe eczema presenting within the first hours to weeks of life is almost universal in HIES. Mucocutaneous candidiasis involving finger and toenails, mouth, vagina and intertriginous areas is seen in most patients. Lung abscesses requiring surgical drainage are almost always staphylococcal. Primary pulmonary infections are predominantly due to *S. aureus* and *Haemophilus influenzae*. These pneumonias are often associated with abscess formation and usually lead to the development of pneumatoceles (Fig. 21.10). Once lung cavities are formed, they provide an attractive environment for superinfection with *Pseudomonas* or *Aspergillus* sp. Thoracotomy is frequently required for removal of pneumatoceles or drainage of infected cavities. For reasons unknown, the unresected lobes of HIES patients often do not expand appropriately to

compensate for the removed segments. Therefore, pneumonectomy or thoracoplasty or both are common in HIES.

Inflammatory bone lesions are relatively common and can be sterile or septic. *Pneumocystis jiroveci* pneumonia, *Cryptococcus neoformans* esophageal infection and intestinal histoplasmosis have been reported.

Characteristic of this syndrome is an extremely elevated serum IgE level, usually >200 IU/mL. However, substantial fluctuations in IgE levels have been recorded in a minority of patients over time, and the levels do not correlate with disease activity or eosinophilia. Abnormal T-cell activation or defective suppressor T-cell function have been suggested to underlie the excess production of IgE. In addition to increased production, there is a decreased fractional catabolic rate for IgE, which further contributes to its extreme elevation. IFN- γ - and TNF- α -producing lymphocytes may be reduced, whereas IL-4 and IL-2 synthesis remains normal. Specific IgE directed against *S. aureus* or *C. albicans* is characteristic of HIES, but serum and secretory IgA for *S. aureus* is very low. Total serum IgG levels are usually within the normal range, whereas serum IgG₄ is elevated. Also, antigen-specific antibody responses are impaired

against both polysaccharide and protein antigens, which may contribute to the increased susceptibility to infections. Eosinophilia is common; the white blood cell count is usually normal to low. Chemotaxis has been found to be intermittently abnormal in some patients studied.

IDENTIFYING THE GENETIC DEFECT IN HYPER-IgE

There is strong evidence for autosomal dominant inheritance of HIES. Linkage analysis of the autosomal dominant phenotype suggested that proximal chromosome 4q contains a disease locus for at least one form of autosomal dominant HIES.²⁶ HIES is likely to be a disease with several genotypes and one predominant phenotype, much as is the case for CGD. Previous efforts to identify a single gene responsible for this phenotype have not yet been successful. A proposed association of atopy (in hyper-IgE and atopic dermatitis) with a gain-of-function mutation in the α subunit of the IL-4 receptor was not substantiated when studied in a large cohort of HIES patients.²⁷ The lymphocytes of patients with hyper-IgE syndrome have recently been shown to have an impaired response to IL-12, resulting in decreased IFN- γ production, possibly accounting for decreased NK-cell activity.²⁸

An autosomal recessive form of HIE has been reported in which the lung lesions are absent but in which CNS vasculitis is common.²⁹

KEY CONCEPTS

HYPER-IgE RECURRENT INFECTION SYNDROME (HIES) OR JOB SYNDROME

- >> Recurrent infections of the lower respiratory system and skin, chronic eczema, extremely elevated IgE levels and eosinophilia are the hallmarks of the syndrome.
- >> Facial, skeletal and dental abnormalities are very common.
- >> Lung abscesses and pneumatocoles following pneumonias caused by *Staphylococcus aureus* and *Haemophilus influenzae* are the major factors for morbidity.

DEFECTS OF THE INTERFERON- γ PATHWAY AND MONOCYTE FUNCTION

The monocyte-macrophage system plays a pivotal role in the host defense against mycobacteria and other intracellular pathogens. Infections with nontuberculous mycobacteria (NTM) in otherwise

Table 21.4 Clinical and laboratory findings in patients with the hyper-IgE syndrome (Adapted from Grimbacher B, Holland SM, Gallin JI, et al.²⁴ Hyper-IgE syndrome disorder. N Engl J Med 1999; 340: 692)

Findings	Incidence (%)
Eczema	100
High IgE levels (>2000IU/ml)	97
Eosinophilia (>2 sd above the mean for normals)	93
Boils	87
Pneumonia	87
Mucocutaneous candidiasis	83
Characteristic facies (in those ≥ 16 years)	83
Lung cysts	77
Scoliosis (for those ≥ 16 years)	76
Hyperextensible joints	68
Delayed shedding of primary teeth	72
Bone fractures	57

low-risk patients have led to the identification of several genetic defects in this critical pathway. The signaling pathways, ligands and their receptors that are responsible for monocyte–macrophage activation and mycobacterial killing are complex but well characterized (Fig. 21.11).

IFN- γ is a pleiotropic cytokine that binds to its receptor (IFN- γ R1) as a homodimer with high affinity, leading to receptor dimerization. Following dimerization of IFN- γ R1, two accessory chains (IFN- γ R2) aggregate with the receptor complex. The two IFN- γ R2 molecules bring two Janus-associated kinase-2 (JAK2) molecules to the vicinity of the JAK1 molecules, which are constitutively associated with IFN- γ R1. The trans-phosphorylation of JAK1 and JAK2 leads to tyrosine

phosphorylation of IFN- γ R1 at position 457. This phosphotyrosine (P-457) forms a docking site for the latent cytosolic signal transducer and activator of transcription-1 (STAT-1) molecule. STAT-1 phosphorylation leads to homodimerization, creating a STAT-1P complex that translocates to the nucleus and initiates the transcription of IFN- γ -regulated genes.

COMPLETE IFN- γ R1 DEFICIENCIES

Genetic susceptibility to mycobacteria and other intracellular pathogens was identified in IFN- γ knockout mice before the disease was identified in humans. In 1996, Newport et al. and Casanova et al. reported a specific mutation in humans predisposing to NTM infection.^{30, 31} The initial patients were related Maltese children with defective macrophage TNF- α production in response to IFN- γ as well as defective antigen processing and presentation. The genetic lesion was found to be an autosomal recessive mutation in the gene encoding IFN- γ R1, leading to a complete absence of IFN- γ R1 on the cell surface. Subsequently, a number of patients with other recessive mutations have been identified.^{32, 33} Common to all patients with autosomal recessive mutations of IFN- γ R1 is that the function of the mutated receptor protein and IFN- γ signaling are severely impaired. Although we think of IFN- γ R1 deficiency as primarily affecting macrophages, the cells with the central role in the pathogenesis of mycobacterial infections, almost all nucleated cells display IFN- γ R. Therefore, subtle aspects of the phenotype probably remain to be defined.

Patients with IFN- γ R1 deficiency usually come to attention because of infections with bacille Calmette–Guérin (BCG) or nontuberculous mycobacteria (NTM) including *M. avium*, *M. fortuitum*, *M. chelonae* and *M. smegmatis*. *Salmonella* spp. infect up to 50% of patients in some series. Mycobacterial disease tends to be diagnosed in infancy or early childhood and leads to death or severe disease. A striking histopathologic finding is the failure to form well-circumscribed tuberculoid granulomas. Although this genetic defect has been predominantly associated with mycobacteria and salmonella, the recognized phenotype has been expanded to include increased susceptibility to cytomegalovirus, respiratory syncytial virus, varicella and parainfluenza virus as well as *Listeria monocytogenes*.³⁴

Fig. 21.9 Facial abnormalities seen in patients with hyper-IgE recurrent infection syndrome (HIES). Protruding prominent mandible and forehead, hypertelorism, broad nasal bridge with a wide nasal tip and increased interalar distance are commonly seen facial features of HIES. (Reproduced with permission from Grimbacher B, Holland SM, Gallin JI, et al. Hyper-IgE syndrome with recurrent infections – an autosomal dominant multisystem disorder. *N Engl J Med* 1999; 340: 692.)

Fig. 21.11 Critical pathways in mycobacterial control. Mycobacterial infection induces IL-12 production by monocytes, which stimulates T cells and NK cells to produce IFN- γ . After binding to its cognate receptor, IFN- γ activates macrophages to produce TNF- α and to kill mycobacteria intracellularly by mechanisms not yet defined. IFN- γ also drives IL-12 production forward. AFB, acid-fast bacilli; NO, nitric oxide; IFN- γ R1, interferon- γ receptor 1; IFN- γ R2, interferon- γ receptor 2; IL-12R β 1 and IL-12R β 2, interleukin-12 receptor chains; TNF- α , tumor necrosis factor- α ; TNF- α R, tumor necrosis factor- α receptors.

PARTIAL IFN- γ R1 DEFICIENCY

Jouanguy et al.³⁵ reported two siblings with autosomal recessive IFN- γ R1 deficiency due to an amino-acid substitution (I87T) in the extracellular domain of the receptor. In contrast to patients with complete IFN- γ R1 deficiency, the partial IFN- γ R1 defect was expressed normally on the cell surface, but only responded to IFN- γ at concentrations 100 times higher than normal. At the cellular level, the defect caused an intermediate phenotype between normal and complete IFN- γ R1 deficiency. The patients were infected with BCG and *Salmonella enteritidis*; one had probable primary tuberculosis. The outcome was favorable compared to that in complete IFN- γ R1 deficiency. These patients formed well-circumscribed and well-differentiated granulomas.

DOMINANT NEGATIVE IFN- γ RECEPTOR 1 DEFICIENCY (AD IFN- γ R1)

A small deletion hot spot in the intracellular domain of IFN- γ R1 causes autosomal dominant susceptibility to mycobacterial infection.³⁶ Patients with this genotype came from diverse ethnic backgrounds and presented with disseminated BCG or NTM infections, histoplasmosis, or salmonellosis. Subsequently, almost all patients with this genotype have developed multifocal NTM osteomyelitis, a manifestation that is rare in the complete IFN- γ R deficiencies. The clinical presentation is usually evident later in childhood than complete IFN- γ R1 deficiency. In addition, AD IFN- γ R1 responds well to antimycobacterials and adjunctive IFN- γ therapy, whereas those with complete defects are often refractory to antibiotics and are unresponsive to IFN- γ .

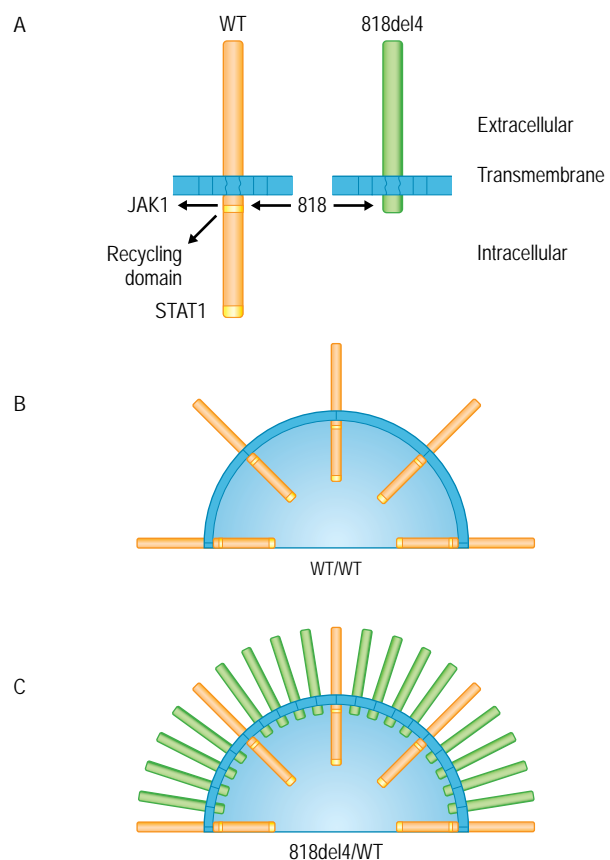

Fig. 21.12 IFN- γ R proteins in wild-type and autosomal dominant conditions. (A) Wild-type IFN- γ receptor with intact intracellular JAK1 and STAT-1 binding sites and recycling domain (left). Truncated IFN- γ R1 molecule due to 818del4/818del. The JAK1 and STAT-1 binding sites and the recycling domain are missing (right). (B) IFN- γ R1 molecules on the surface of cells homozygous for wild type. (C) Mutant IFN- γ R1 molecules on the surface of cells heterozygous for 818del4 and wild-type IFN- γ R1 alleles. Excess truncated receptors are found on the surface of 818del4/WT cells compared to normal receptors at WT/WT cell surface due to the lack of the recycling motif. Signaling is impaired due to the lack of intracellular signaling domains. (Modified from Jouanguy E, Lamhamedi-Cherradi S, Lammas D, et al. IFNGR1 small deletion hotspot associated with dominant susceptibility to mycobacterial infection. *Nature Genet* 1999; 21: 370.)

The genetic lesion can be one of four independent mutation events at a single mutation site: 816del4, 817del4, 818del4 (designated 818del4, as they cannot be distinguished from each other), or 818delT or 819delT (designated 818delT). These deletions result in frameshifts leading to a premature stop and early termination of the protein. The defect is localized to exon 6 in the IFN- γ R1 open reading frame, within the intracytoplasmic segment of the receptor. Because the JAK1 and STAT-1 binding motifs are deleted, mutant chains are unable to transduce the IFN- γ signal. Mutant proteins are overexpressed at the cell surface due to a lack of the receptor-recycling domain, which is adjacent to the

JAK1-binding domain (Fig. 21.12). These overabundant mutant receptors compete with wild-type receptors for binding IFN- γ . Near normal binding affinity to its ligand, defective signaling and impaired recycling combine to exert the dominant negative effect.

Flow-cytometric analysis of mononuclear cells from affected patients demonstrates a three- to fivefold increase in IFN- γ R1 density compared to normal individuals. This laboratory finding supports the fact that recycling of the mutant receptor is defective. At the histologic level, patients with AD IFN- γ R1 form paucibacillary and mature-looking granulomas in response to BCG, similar to those with partial recessive deficiency. At the cellular level, the response to IFN- γ as evaluated by HLA-DR expression and phosphorylation of STAT-1 requires 100–1000-fold higher concentrations of IFN- γ than do normal cells. Intracellular detection of STAT-1 phosphorylation via flow cytometry in response to IFN- γ stimulation allows cell-specific determination of IFN- γ R integrity.³⁷

These patients respond well to antimycobacterial agents. Administration of IFN- γ at doses of 50 μ g/m² subcutaneously, 3 days weekly, accentuates the effects of antimycobacterial agents. There have been anecdotal reports of the need to use much higher doses of IFN- γ *in vivo* to achieve a therapeutic effect.

COMPLETE IFN- γ R2 DEFICIENCY

The clinical presentation of complete IFN- γ R2 deficiency is similar to that of complete IFN- γ R1 deficiency, with early onset of severe systemic mycobacterial infections and impaired granuloma formation.³⁸ Mutational analysis has shown homozygous mutations resulting in premature stop codons and missense mutations. As in complete IFN- γ R1 deficiency, complete IFN- γ R2 deficiency causes a lack of cellular response to IFN- γ .³⁹

IL-12p40 DEFICIENCY

IL-12p40 deficiency is associated with disseminated BCG infection and *S. enteritidis* sepsis.⁴⁰ Patients have homozygous autosomal recessive deletions in the gene encoding IL-12p40. Neither IL-12p40 nor IL-12p70 subunits are detectable. Patient's lymphocytes secrete less IFN- γ , which can be corrected with recombinant IL-12 *in vitro*.

This is a milder disease than complete IFN- γ R1 or IFN- γ R2 deficiencies, as residual, IL-12-independent IFN- γ secretion persists, as reflected in the capacity to form organized granulomas.⁴¹

IL-12 RECEPTOR β 1 MUTATIONS

Following the identification of patients with IFN- γ R1 and IFN- γ R2 mutations, several patients with disseminated mycobacterial and *Salmonella* infections and defective IL-12 receptor β 1 (IL-12R β 1)⁴² chains were reported. The clinical phenotype includes severe, recurrent, disseminated *Salmonella* and NTM infections or progressive BCG infection following vaccination. Granulomatous infiltrates tend to be contained and well organized. Patients usually respond to antibiotic therapy with recovery. Most patients with IL-12R mutation lack cell surface expression of the receptor. As a result of defective IL-12R signaling, IFN- γ is produced at low levels by T cells and NK cells, thereby predisposing to infections with *Salmonella* and NTM.

Genetic lesions have been detected in the extracellular domains of the IL-12R β 1 leading to premature stop codons and early termination of the

protein. All reported patients with IL-12R β 1 mutations show an autosomal recessive inheritance pattern, whereas heterozygous carriers are clinically healthy with normal IL-12 signaling and IFN- γ production.

Patients usually respond well to antimicrobials. Those that are not cured of infections with antimicrobials alone may benefit from exogenous IFN- γ therapy.^{43,44}

Mast cells, basophils and mastocytosis

Martin Metz, Knut Brockow, Dean D. Metcalfe,
Stephen J. Galli

22

Mast cells and basophils are critical effector cells in IgE-associated allergic diseases and in host responses to parasites, as well as in a variety of other processes.¹⁻³ Mast cells and basophils share several features in addition to the metachromatic staining properties of their prominent cytoplasmic granules (Table 22.1). Both are derived from bone marrow progenitors, express high-affinity IgE Fc receptors (FcεRI) on their surface, are major sources of histamine and other potent inflammatory mediators, and can be activated to release a wide array of mediators after sensitization with IgE and subsequent exposure to specific multivalent antigen.¹⁻⁴ However, mast cells and basophils differ in their responsiveness to other potential activators of secretion and in the specific pattern of mediators released by the activated cells.¹⁻³ Moreover, basophils and mast cells exhibit several differences in morphology, particularly by transmission electron microscopy (Table 22.2 and Fig. 22.1).

DEVELOPMENT AND DISTRIBUTION OF MAST CELLS

DISTRIBUTION AND HETEROGENEITY

Unlike mature basophils, mature mast cells do not normally circulate in the blood but are ordinarily distributed throughout the connective tissues, where they often lie adjacent to blood and lymphatic vessels, near or within nerves, and beneath epithelial surfaces that are exposed to the external environment (e.g., lung, gut and skin).¹⁻³

The numbers of mast cells in normal tissues vary considerably by anatomic site, and their distribution can change during perturbations of homeostasis.¹⁻³ For example, in certain inflammatory or immunologic reactions mast cells can appear within the respiratory or gastrointestinal epithelium and in their associated secretions.¹⁻³ Mast cell numbers at sites of chronic inflammation may be many times higher than in the corresponding normal tissues.¹⁻³ The extent to which such changes reflect proliferation of resident mast cell populations, as opposed to the recruitment and differentiation of mast cell precursors, remains unclear.

The phenotype of different populations of mast cells, including morphology, histochemistry, mediator content and response to drugs and stimuli of activation, can also vary.¹⁻³ It is possible that mast cells of

different phenotypes have different roles in health and disease, and may respond differently to drugs used in clinical settings. In mice and rats, connective tissue mast cells (CTMCs) and mucosal mast cells (MMC)s exhibit significant differences in multiple aspects of phenotype.¹⁻³ In humans, some mast cells express immunoreactivity for both tryptase and chymase (MC_{TC}), whereas others are immunoreactive for tryptase (MC_T) but lack detectable chymase (<0.04 pg/cell).^{1,3} MC_T predominate in lung and small intestinal mucosa and MC_{TC} predominate in skin and small intestinal submucosa. A few mast cells that apparently express chymase (MC_C) but no detectable tryptase have also been reported.

Mast cell phenotypic variation could reflect any one or more of the following mechanisms: distinct mast cell lineages; the process of cellular maturation and differentiation; the functional status of the cell; and the influence of microenvironmental factors.³

KEY CONCEPTS

ORIGINS OF BASOPHILS AND MAST CELLS

- >> Mast cells and basophils represent distinct hematopoietic lineages.
- >> Basophils are granulocytes that mature in the bone marrow, circulate in the blood, and can be recruited into peripheral tissues at sites of immunologic or pathologic responses.
- >> Mast cell progenitors also arise in the bone marrow, but mast cells mature in peripheral tissues.
- >> Mast cells are present throughout virtually all normal connective tissues, and are particularly abundant near epithelial surfaces exposed to the environment.
- >> The KIT ligand stem cell factor (SCF) is critical for mast cell development and survival and can influence mast cell function.
- >> IL-3 is not required for normal basophil development in mice, but is critical for the basophilia associated with Th2 responses.

Table 22.1 Natural history, major mediators and surface membrane structures of human mast cells and basophils

Characteristic	Basophils	Mast cells
Natural history		
Origin of precursor cells	Bone marrow	Bone marrow
Site of maturation	Bone marrow	Connective tissues (a few in the bone marrow)
Mature cells in the circulation	Yes (usually <1% of blood leukocytes)	No
Mature cells recruited into tissues from circulation	Yes (during immunologic, inflammatory responses)	No
Mature cells normally residing in connective tissues	No (not detectable by microscopy)	Yes
Proliferative ability of morphologically mature cells	None reported	Yes (under certain circumstances)
Life span	Days (like other granulocytes)	Weeks to months (based on studies in rodents)
Mediators		
Major mediators stored preformed in cytoplasm	Histamine, chondroitin sulfates, neutral protease with bradykinin-generating activity, β -glucuronidase, elastase, cathepsin G-like enzyme, major basic protein, Charcot-Leyden crystal protein, tryptase ^a , chymase ^a , carboxypeptidase A ^a	Histamine, heparin and/or chondroitin sulfates, neutral proteases (chymase and/or tryptase), many acid hydrolases, cathepsin G, carboxypeptidase
Major lipid mediators produced upon appropriate activation	Leukotriene C ₄ (LTC ₄)	Prostaglandin D ₂ , LTC ₄ , platelet-activating factor
Cytokines, chemokines and growth factors released upon appropriate activation	IL-4, IL-13	Tumor necrosis factor, IL-3, IL-4, IL-5, IL-6, IL-10, IL-13, IL-16, VPF/VEGF, GM-CSF, MIP-1 α , MCP-1
Surface structures^b		
Ig receptors	Fc ϵ RI, Fc γ RII (CDw32)	Fc ϵ RI, Fc γ RI, Fc γ RII
Cytokine/growth factor receptors	IL-1RIIb (CD121b), IL-2R (CD25), IL-3R α , IL-4R α , IL-5R α , GM-CSFR α , Trk-A, CCR-2, CCR-3, CXCR1, CXCR4, KIT (some basophils express low numbers of KIT receptors)	KIT (SCF receptor), CCR-3, CCR-5, CXCR1, CXCR2, CXCR3, CXCR4, IL-4R α , IL5R α , IL-6R, IFN- γ R α , TrkA
Cell adhesion structures	LFA-1 α chain (CD11a), C3bi receptor (CD11b), CR4 (CD11c), sLe ^x (CD15s), LFA-1 β chain (CD18), β_1 integrin (CD29), leukosialin (CD43), PECAM-1 (CD31), CD44, ICAM-3 (CD50), ICAM-1 (CD54), LFA-3 (CD58), L-selectin (CD62L), CD102, β_7 -integrin, neurothelin (CD147), PETA-3 (CD151), BST-1 (CD157), PSGL-1 (CD162)	CD11a, CD11b, CD11c, CD18, CD29, CD43, CD44, CD49a, CD49b, CD49c, CD49d, CD49e, CD50, CD51, CD54, CD58, CD61, CD81, CD102, CD147, CD151, CD157

IL, interleukin; SCF, stem cell factor; LFA, lymphocyte function-associated antigen; CR, complement receptor; ICAM, intercellular adhesion molecule; sLe^x sialyl Lewis^x; PECAM-1, platelet-endothelial cell adhesion molecule-1; PETA-3, platelet-endothelial cell tetra-span antigen; BST-1, bone marrow stromal cell antigen-1; PSGL-1, P-selectin glycoprotein ligand-1.

^aExpressed in peripheral blood basophils of asthma, allergy, and drug-reactive patients (Li L, Li y, Reddel SW, et al. Identification of basophilic cells that express mast cell granule proteases in the peripheral blood of asthma, allergy, and drug-reactive patients. J Immunol 1998; 161: 5079–5086).

^bSome mast cell surface structures have been detected in either mast cells cultured from human umbilical cord blood (expression varies during differentiation), skin mast cells or lung mast cells (Valent P. Immunophenotypic characterization of human basophils and mast cells. Chem Immunol 1995; 61: 34–48). Basophils and various populations of mast cells also can express several TLRs.^{7,14}

MAST CELL DEVELOPMENT IN MICE AND RATS

An essentially homogeneous population of growth factor-dependent immature mast cells develops when mouse hematopoietic cells are cultured in media containing interleukin (IL)-3.³ Although such IL-3-induced bone marrow-derived cultured mast cells (BMCs) share some phenotypic

characteristics with mouse MMCs, both *in vivo* and *in vitro* studies indicate that these cells acquire phenotypic features more similar to those of CTMCs when placed in an appropriate environment.^{1–3} *In vitro*, fibroblasts provide factors, particularly stem cell factor (SCF), that promote IL-3-induced BMCs to develop features of CTMCs.^{1–3} Indeed, studies in both mice and humans indicate that many aspects of mast cell development

Table 22.2 Morphologic features of mature basophils and mast cells (From Galli SJ, Lichtenstein LM. In: Middleton E Jr, Reed CE, Ellis EF, et al., eds. Allergy: principles and practice, 3rd edn. St Louis: Mosby, 1988; with permission from Elsevier.)

Characteristic	Basophils	Mast cells
Size	5–7 μm	6–12 μm
Surface	Irregular, short, thick processes	Numerous, uniformly distributed, elongated thin processes
Nucleus	Segmented (usually; occasionally nonsegmented)	Nonsegmented (usually round to oval in electron micrographs) ^a
Nuclear chromatin condensation	Marked	Moderate
Cytoplasmic granules	Fewer and larger than in mast cells; contain predominantly electron-dense particulate material with occasional membranous whorls	Smaller, more numerous, and generally more variable than in basophils; contain scroll-like structures, particles, or crystals, alone or in combination
Aggregates of cytoplasmic glycogen	Present	Absent
Cytoplasmic lipid bodies	Rare	Common but not present in all cells
Granule–granule fusion during anaphylactic degranulation	Rare (granule membranes usually fuse individually with plasma membrane)	Common

^aHuman mast cells generated *in vitro* can exhibit multilobulated nuclei.

Fig. 22.1 Mast cell and basophil ultrastructure. A basophil (B) adjacent to a mast cell (MC) in the ileal submucosa of a patient with Crohn disease. The basophil exhibits a bilobed nucleus (solid arrows) whose chromatin is strikingly condensed beneath the nuclear membrane. The basophil surface is relatively smooth with a few blunt processes (arrowhead). The mast cell nucleus is larger and its chromatin less condensed than that of the basophil. The mast cell's granules are smaller, more numerous and more variable in shape and content than those of the basophil. The mast cell surface has numerous elongated, thin folds (curved arrows). (Original magnification $\sim \times 9000$). (From Dvorak AM, Monahan RA, Osage JE, Dickens GR. Crohn's disease: transmission electron microscopic studies. Hum Pathol 1980; 11: 606–619, with permission from Ann M. Dvorak.)

and survival are critically regulated by SCF, the ligand for the KIT tyrosine growth factor receptor, which is expressed on the mast cell surface.^{1–3} Several other cytokines also promote mast cell development and/or proliferation *in vitro*, including IL-4, IL-9 and IL-10.^{1–3} In contrast, granulocyte–macrophage colony-stimulating factor (GM-CSF) and transforming growth factor (TGF)- β_1 can inhibit mouse BMCMC proliferation in response to IL-3.^{1–3}

MAST CELL DEVELOPMENT IN HUMANS

Human mast cell progenitors are present in umbilical cord blood, as well as in the bone marrow and the peripheral blood, and highly enriched populations of mast cells develop from these and other sources of human hematopoietic cells when they are maintained *in vitro* in media containing recombinant human SCF (rhSCF).^{1–3, 5} rhSCF also promotes the development of human mast cells *in vivo*.⁶

DEVELOPMENT AND DISTRIBUTION OF BASOPHILS

Basophils differentiate and mature in the bone marrow and then circulate in the blood. In the blood, the basophil is the least common blood granulocyte, with a prevalence of approximately 0.5% of total leukocytes and approximately 0.3% of nucleated marrow cells.³ Basophils are not ordinarily found in connective tissues. Because the normal frequency of blood and bone marrow basophils is so low, accurate determinations ordinarily require absolute counting methods. The basophil's prominent metachromatic cytoplasmic granules permit it to be identified easily in Wright–Giemsa-stained preparations of peripheral blood or bone marrow cells. Both cytogenetic evidence and *in vitro* studies indicate that basophils share a precursor with other granulocytes and monocytes.³ The ultrastructural features of human basophils are summarized in Table 22.2 and illustrated in Fig. 22.1. The extent of the biochemical similarities between basophils and mast cells continues to be explored.⁷ Under physiological conditions basophils have a lifespan measured in days. IL-3 promotes the production and survival of basophils *in vitro* and can induce basophilia *in vivo*. Findings in IL-3^{–/–} mice indicate that IL-3 is not necessary for the development of normal numbers of bone marrow or blood basophils, but is essential for the bone marrow and blood basophilia associated with certain Th2 cell-associated immunologic responses.^{2, 8}

BIOLOGIC MEDIATORS PRODUCED BY MAST CELLS AND BASOPHILS

Basophils and mast cells contain, or elaborate on appropriate stimulation, a diverse array of potent biologically active mediators.^{1-3, 7} These agents mediate a wide array of effects in inflammation, immunity and tissue remodeling, and can also influence the clotting, fibrinolytic, complement and kinin systems. Some of these products are stored pre-formed in cytoplasmic granules (e.g. proteoglycans, proteases, histamine, certain cytokines), and others are synthesized upon activation of the cell by IgE and antigen or other stimuli (e.g., products of arachidonic acid oxidation through the cyclo-oxygenase or lipoxygenase pathways and, in some cells, platelet-activating factor [PAF], cytokines, chemokines, and growth factors).^{1-3, 7}

MEDIATORS THAT ARE PRE-FORMED

Mediators stored pre-formed in the cytoplasmic granules include histamine, proteoglycans, serine proteases, carboxypeptidase A, and small amounts of sulfatases and exoglycosidases. Studies in mice indicate that

mast cells account for nearly all of the histamine stored in normal tissues, with the exception of the glandular stomach and the CNS.³ Basophils are the source of most of the histamine in normal human blood.³ Mouse and rat mast cells, but not human mast cells or basophils, contain significant quantities of serotonin.^{1, 3}

Human mast cells contain variable mixtures of heparin (about 60 kDa) and chondroitin sulfate proteoglycans.^{1, 3} Although the sulfated glycosaminoglycans of normal human blood basophils have not been characterized, chondroitin sulfates account for the majority of the proteoglycans in the basophils of patients with myelogenous leukemia.³

Neutral proteases are the major protein component of mast cell secretory granules. The three major families of proteases found in mast cell granules are represented by the serine proteases chymase and tryptase and the metalloprotease carboxypeptidase A. In mice, five different chymases (mouse mast cell protease [mMCP]-1, -2, -4, -5 and -9) and four different tryptases (mMCP-6, -7 and -11 and mouse transmembrane tryptase [mTMT]) have been described.^{9, 10} In humans, it appears that there is only one chymase and four different tryptases (α , β , γ and δ , encoded by several genes and alleles).⁹⁻¹¹ Mast cell protease content varies depending on the microenvironment, and can therefore contribute significantly to mast cell heterogeneity. Several potential functions have been associated with various mast cell proteases (e.g., effects that promote bronchomotor tone and degradation of fibrinogen, extracellular matrix proteins and endogenous or exogenous peptides),^{9, 10, 12} and it is likely that additional biological roles will be identified.

KEY CONCEPTS

MAST CELL AND BASOPHIL MEDIATORS

- >> Mast cells and basophils are sources of distinct, but overlapping, panels of mediators with diverse biologic effects.
- >> Some mast cell and basophil mediators are preformed and stored in cytoplasmic granules (e.g., histamine, heparin and other proteoglycans, proteases). They can be released rapidly upon degranulation induced by cellular activation.
- >> Mast cells and basophils also produce lipid mediators (e.g., PGD₂, LTC₄), which are derived from arachidonic acid and are newly synthesized upon appropriate activation of the cell.
- >> Mast cells can transcribe and secrete many cytokines/chemokines/growth factors, including (in mouse and/or human mast cells) IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-13, IL-16, GM-CSF, TNF, IFN- γ , TGF- β , bFGF, VPF/VEGF, NGF and many C-C chemokines.
- >> In response to cellular activation (e.g., through the Fc ϵ RI), mast cells can release at least two cytokines, TNF and VPF/VEGF, from both stored and newly synthesized pools.
- >> Induction of cytokine mRNA in mast cells is not always accompanied by the release of detectable cytokine bioactivity.
- >> Under some circumstances, induction and/or release of mast cell cytokines can occur in response to stimuli that do not induce a detectable release of histamine.
- >> Release of some cytokines (e.g., TNF) can continue for hours after initial Fc ϵ RI-dependent mast cell activation.
- >> Mast cell cytokine mRNA expression and/or cytokine release can be inhibited by cyclosporine A or dexamethasone.
- >> Basophils appear to produce a more restricted spectrum of cytokines than do mast cells, but these include IL-4 and IL-13.

MEDIATORS THAT ARE NEWLY SYNTHESIZED

Activated mast cells initiate the de novo synthesis of several lipid-derived substances. Of particular importance are the cyclo-oxygenase and lipoxygenase metabolites of arachidonic acid, which have potent inflammatory activities and which may also play a role in modulating the release process itself. The major cyclo-oxygenase product of mast cells is prostaglandin D₂ (PGD₂), and the major lipoxygenase products derived from mast cells and basophils are the sulfidopeptide leukotriene LTC₄ and its peptidolytic derivatives LTD₄ and LTE₄.^{1-3, 7, 13} Mast cells isolated from a variety of tissues release both LTC₄ and PGD₂, whereas peripheral blood basophils release LTC₄ but not PGD₂. Mast cells also produce LTB₄, although in much smaller quantities than PGD₂ or LTC₄, and some mast cell populations represent a potential source of PAF.^{1-3, 7, 13}

CYTOKINES, CHEMOKINES AND GROWTH FACTORS

The ability of mast cells and basophils to produce cytokines, chemokines and growth factors greatly expands the list of possible mechanisms by which these cells may contribute to the pathophysiology of allergic and immunologic diseases, host defense or homeostasis.^{1-3, 7} Mast cells are a source for IL-1, -2, -3, -4, -5, -6, -8, -10, -13, -16, GM-CSF, TNF, NGF, bFGF and VPF/VEGF, as well as several C-C chemokines (Chapters 10 and 11). These products are released when the cells are activated via IgE-dependent mechanisms, and are also produced under other circumstances (e.g., in response to stimulation by bacterial products).^{1-3, 7, 14}

The first cytokine bioactivity to be clearly associated with normal mast cells was TNF.^{2, 3} Some of the TNF released from mouse mast cells upon appropriate stimulation (e.g., via IgE-dependent activation)

reflects cytokine that is rapidly released from pre-formed stores, and even larger amounts of newly synthesized TNF are released over a period of hours after cell activation.

The first cytokine bioactivity to be associated with normal basophils was IL-4, and mature human basophils isolated from peripheral blood can release IL-4 (and IL-13) in response to FcεRI-dependent activation.^{2,3,15} It is possible that IL-4 derived from mast cells or basophils at sites of allergic inflammation can promote T-cell differentiation toward a Th2 phenotype. Basophils and mast cells express CD40 ligand (CD40L, CD154), and thus may also contribute to IgE production by promoting immunoglobulin class switching.^{2,7,16}

MECHANISMS OF ACTIVATION OF MAST CELLS AND BASOPHILS

FcεRI-MEDIATED ACTIVATION

Mast cells and basophils express FcεRI, the high-affinity receptor for IgE.¹⁻⁴ Whereas high 'constitutive' levels of FcεRI expression apparently are restricted to mast cells and basophils, in humans low levels of expression are detected in Langerhans' cells, peripheral blood dendritic cells and monocytes.¹⁻⁴ In mast cells and basophils, FcεRI has a tetrameric structure composed of a single IgE-binding α chain, a single β chain and two identical disulfide-linked γ chains. All three subunits must be present for efficient cell surface expression in rodents, but human cells can express FcεRI in the absence of the β chain. In humans, the FcεRI expressed by hematopoietic cells other than mast cells and basophils consists of only the αγ form.⁴ The aggregation of FcεRI that is occupied by IgE is sufficient for initiating downstream signal transduction events that activate the mast cells or basophils to degranulate and to secrete lipid mediators and cytokines.¹⁻⁴ The FcεRI β chain functions as an amplifier of signaling through FcεRI, which can markedly upregulate the magnitude of the mediator release response to FcεRI aggregation.⁴ Certain mutations that result in amino acid substitutions in the human β chain may be linked to atopic disease.⁴

At the ultrastructural level, stimulation of appropriately sensitized human basophils with specific antigen provokes fusion of the membranes enveloping individual cytoplasmic granules with the plasma membrane³ (Fig. 22.2). As a result, the granules' contents, including stored mediators, are released via multiple narrow communications between single granules and the cell surface. IgE-dependent degranulation of human lung mast cells also results in the fusion of granule membranes with the plasma membrane³ (Fig. 22.3). However, in this cell type the first ultrastructural changes detectable in the stimulated cells are granule swelling, followed by fusion of individual granule membranes forming interconnecting chains of swollen granules; histamine release is initiated by the opening of these channels to the exterior through multiple narrow points of fusion with the plasma membrane.³

Both *in vitro* and *in vivo*, levels of FcεRI surface expression on mast cells and basophils correlates positively with the concentration of IgE.^{2,16} IgE-dependent upregulation of FcεRI expression *in vitro*, which reflects stabilization of expression of FcεRI on the cell surface, permits mast cells to secrete strikingly increased amounts of mediators after anti-IgE challenge, and to exhibit IgE-dependent mediator release at lower concentrations of specific antigen. Furthermore, mast cells that have undergone IgE-dependent upregulation of surface FcεRI expression may,

upon subsequent FcεRI-dependent activation, secrete cytokines and growth factors that are released at very low levels (or not at all) by mast cells with low levels of FcεRI expression.^{2,16} These findings strongly suggest that basophils and mast cells in subjects with high levels of IgE (as typically characterizes patients with allergic disorders or parasitic infections) may be significantly enhanced in their ability to express IgE-dependent effector functions or, via cytokine production, potential immunoregulatory functions.^{2,16} Recent *in vitro* data from studies with mouse or human mast cells indicates that, under some circumstances, the binding of certain IgE antibodies to FcεRI can promote mast cell survival and/or mediator secretion, even in the absence of known specific antigen.^{2,16} The clinical significance of these findings is not yet clear.

In addition to the high-affinity IgE receptor, mouse mast cells and human basophils express the low-affinity IgG receptor FcγRIIB. Co-aggregation of FcγRIIB and FcεRI has been shown to diminish IgE-dependent activation of mouse mast cells, RBL cells and human basophils *in vitro* and to diminish the expression of IgE- and mast cell-dependent allergic reactions *in vivo*.¹⁷

ACTIVATION BY NONIMMUNOLOGIC MEANS

In addition to IgE and specific antigen, a variety of biologic substances, including products of complement activation and neuropeptides, as well as certain bacterial products, cytokines, animal venom components, chemical agents and physical stimuli, elicit the release of basophil or mast cell mediators.^{1-3, 11, 14} Morphine and other narcotics are among the pharmacological agents that can induce the release of mast cell mediators, especially from skin mast cells, and intravenous infusion of large

KEY CONCEPTS

MECHANISMS OF MAST CELL AND BASOPHIL ACTIVATION

- Mast cells and basophils have cell-surface high-affinity IgE receptors (FcεRI) that confer on these cells the ability to express specific immunological functions.
- Mast cells and basophils can be activated *in vivo* either by signaling through the FcεRI or by a variety of nonimmunologic signals (e.g., certain neuropeptides, anaphylatoxins, f-Met-Leu-Phe, bacterial products/TLR ligands, animal venom components).
- The responses of basophils and/or different subpopulations of mast cells to stimuli other than IgE and antigen vary: some populations respond weakly or not at all to some stimuli.
- Some stimuli activate cells to release a panel of mediators quantitatively or qualitatively more limited than that induced by IgE and antigen.
- The susceptibility of mast cells or basophils to activation by IgE and specific antigen or other stimuli can be regulated by cytokines (e.g., SCF, IL-3), as well as other by microenvironmental factors.
- Certain mast cell populations can exhibit down-regulation of FcεRI-dependent activation via signaling by FcγRIIb or other receptors (such as members of the KIR family).

Fig. 22.2 (A) Transmission electron micrograph of a human basophil in a preparation of peripheral blood leukocytes obtained by separation over Ficoll-Hypaque. All of the cytoplasmic granules (some indicated by solid arrows) contain particulate electron-dense material. N, nucleus. (Original magnification $\sim \times 19800$). (B) A human basophil 2 minutes after exposure to antigen *in vitro*. The cell exhibits extrusion of granules from six separate sites on the plasma membrane (small arrows). At this time after cell stimulation, particle-filled granules retain their shape and characteristic structure even after exposure to extracellular milieu. Cationized ferritin coats the cell surface and enters cula de sac that contain exteriorized granules. The cell exhibits no fully intracytoplasmic typical basophilic granules, but one of the smaller kind of granules (curved arrow) can be observed in perinuclear region. N, nucleus. (Original magnification $\sim \times 19200$). (From Dvorak AM, Newball HH, Dvorak HF, Lichtenstein LM. Antigen-induced IgE-mediated degranulation of human basophils. *Lab Invest* 1980; 43: 126-139, with permission from Nature Publishing Group Ltd.)

doses of morphine regularly causes an increase in plasma histamine levels and often results in shock.^{1,3}

HIV glycoprotein 120, as well as protein Fv (pFv), which is released into the intestinal tract in patients with viral hepatitis, can interact with the heavy-chain variable domain of IgE antibodies that use V_{H3} gene segments (Chapter 4) and thereby induce the release of histamine, IL-4 and IL-13 from human basophils and mast cells.⁷ Basophils also respond to stimulation with immobilized secretory IgA (sIgA) by releasing both histamine and LTC₄, but only if the cells have first been primed by pretreatment with IL-3, IL-5 or GM-CSF.¹⁸ Furthermore, certain bacterial products – including lipopolysaccharide (LPS) and other ligands of TLRs – directly induce the release of some mast cell products; pathogens can also activate mast cells indirectly via activation of the complement system.^{2,3,14}

It should be emphasized that the responsiveness of basophils and different populations of mast cells to individual stimuli varies, e.g., cutaneous mast cells appear to be much more sensitive to stimulation by neuropeptides than are pulmonary mast cells.¹⁻³ Moreover, some stimuli induce a pattern of mediator release that differs from the one associated with IgE-dependent mast cell activation. For example, LPS

induces mast cells to release certain cytokines preferentially over pre-formed mediators.¹⁴

MAST CELLS, BASOPHILS AND ALLERGIC INFLAMMATION

The immediate hypersensitivity reaction is the pathophysiologic hallmark of allergic rhinitis, allergic asthma and anaphylaxis, and the central role of the mast cell in the pathogenesis of the acute manifestations of these disorders is widely accepted. To avoid confusion between immunologic mechanisms and clinical syndromes in the discussion of these disorders, it is essential to begin by defining some key terms.

TYPE I HYPERSENSITIVITY REACTION

Also known as the allergic or immediate hypersensitivity reaction, a type I hypersensitivity reaction, as originally described by Gell and Coombs, is now understood to be a pathologic immune response initiated in

Fig. 22.3 (A) Mast cell purified from human lung. The cell contains many cytoplasmic granules with scroll-like substructural elements (solid arrows) and eight large nonmembrane-bound lipid bodies (open arrows). The plasma membrane has prominent folds. N, nucleus. (Original magnification $\sim \times 12\,900$). (B) An isolated human lung mast cell 10 minutes after exposure to anti-IgE *in vitro*. Some degranulation channels (C), formed by fusion of membranes surrounding individual cytoplasmic granules, contain altered granule matrix; others (EC) are empty. Cationized ferritin stains the plasma membrane and the membranes of some empty degranulation channels (EC). The membranes lining other channels (C) are unstained. A few unaltered scroll-containing granules (solid arrows) remain. Numerous lipid bodies are also present (open arrows). The cytoplasm contains prominent filaments. N, nucleus. (Original magnification $\sim \times 9100$). (From Galli SJ, Dvorak AM, Dvorak HF. *Prog Allergy* 1984; 34: 1, with permission from Ann M. Dvorak.)

appropriately sensitized subjects by the interaction of antigen-specific IgE molecules on the surface of mast cells and/or basophils with the relevant multivalent antigen.^{1-3,16} The physiologic effects are due to the biologic responses of target cells (vascular endothelial cells, smooth muscle, glands, leukocytes, etc.) to mediators released by activated mast cells and/or basophils. The term refers to an immunopathologic mechanism: it conveys no information about the severity or distribution of the reaction.

IMMEDIATE- OR EARLY-PHASE RESPONSES

The signs and symptoms that develop at the site of antigen exposure within the first few minutes of a type I reaction reflect the biologic activities of the mast cell- and/or (especially in systemic reactions) basophil-derived mediators that are released immediately after the activation of these cells. In

sites that do not contain basophils, such as normal skin, these mediators are derived largely – perhaps exclusively – from mast cells. Thus, in most allergic patients intradermal challenge with specific antigen or anti-IgE induces an immediate wheal and flare reaction, accompanied by intense pruritus, which reaches a maximum 15–30 minutes later.^{1-3,16} Such immediate allergic reactions are usually accompanied by an increase in local levels of LTC₄ and PGD₂, and by the liberation of histamine and tryptase.

Studies in wild-type and *c-kit* mutant genetically mast cell-deficient mice, and *c-kit* mutant mice that have been selectively engrafted with mast cell populations (i.e., mast cell knock-in mice), have shown that essentially all of the augmented vascular permeability, tissue swelling and deposition of cross-linked fibrin associated with IgE-dependent passive cutaneous anaphylaxis reactions or with IgE-dependent reactions in the stomach wall were mast cell dependent.^{2,16} In humans, studies of nasal secretions or skin blister fluids induced by exposure to

CLINICAL RELEVANCE

MAST CELLS AND BASOPHILS IN HEALTH AND DISEASE

- >> Mast cells and basophils are primary effector cells in atopic disorders (allergic rhinitis, allergic asthma, anaphylaxis).
- >> Antigen-specific mast cell activation results in an immediate reaction, and in many cases contributes to a late-phase response in the involved tissues.
- >> The late consequences of mast cell activation reflect the actions of cytokines, chemokines, growth factors and other mediators derived from mast cells and from other cells resident at or recruited to these sites whose recruitment, phenotype or function can be influenced by mast cell-derived products.
- >> Mast cells and basophils may also contribute to host defense against certain parasites and have been implicated in a wide variety of other diseases and host responses, including innate immunity to microbial infection.

allergen demonstrate the release of both histamine and tryptase, with a strong correlation between levels of these two mediators, implicating mast cells in these reactions.¹⁶

ANAPHYLAXIS

Traditionally, this term has been used to describe an antigen-specific IgE-mediated reaction that is both life-threatening and systemic, with several organ systems involved¹⁹ (Chapter 42). In this context anaphylaxis can be considered a severe, systemic type I immediate hypersensitivity reaction. However, because degranulation of mast cells and/or basophils can occur via non-IgE-dependent mechanisms, and because the biologic effects of the liberated mast cell and/or basophil mediators are the same regardless of the mechanism by which they are released, the term anaphylaxis sometimes also is used to describe a clinical syndrome that is severe, abrupt, and manifested by cutaneous (urticaria, angioedema), respiratory (asthma, laryngeal edema), cardiovascular (hypotension, cardiovascular collapse) and/or gastrointestinal (nausea, vomiting, diarrhea, cramping) signs and symptoms that occur either singly or in combination, whether or not the underlying mechanism is dependent on IgE.¹⁹ When used in this fashion, the term does not imply any particular pathologic mechanism. Several lines of evidence indicate that systemic anaphylaxis in humans is associated with extensive mast cell activation. Increased levels of mast cell tryptase have been detected in the serum after the onset of anaphylactic symptoms, but little or no tryptase can be detected in serum from normal controls.¹¹ The histamine detected in the plasma of patients with anaphylaxis can be derived from both mast cells and basophils.¹⁻³

LATE-PHASE RESPONSES

In many allergic patients the immediate reaction to cutaneous antigenic challenge is followed 4–8 hours later by persistent swelling and leukocyte infiltration, which is termed the late-phase response (LPR).^{1-3, 16} LPRs can develop following IgE-dependent reactions in the respiratory tract, the nose and the skin, and in other anatomic locations. Many of the

clinically significant consequences of IgE-dependent reactions, both in the respiratory tract and in the skin, are thought to reflect the actions of the leukocytes recruited to these sites, rather than the direct effects of the mediators released by mast cells at early intervals after antigen challenge.

Both clinical and animal studies suggest that mast cell activation contributes to the leukocyte infiltration that is associated with LPRs, via effects of mast cell products on adhesion molecule expression by vascular endothelial cells and other cells at the reaction site, as well as by the production of chemokines and other chemoattractants.^{1-3, 7, 11, 16} However, in actively sensitized hosts, LPRs can be induced by peptides that can activate T cells but which cannot induce IgE-dependent mast cell activation.²⁰ Such evidence indicates that both IgE- and T cell-dependent mechanisms can contribute to the elicitation of LPRs in actively immunized subjects.

The leukocytes recruited to sites of experimentally induced LPRs include basophils, eosinophils, neutrophils, lymphocytes and macrophages. Thus, the expression of features of LPRs reflects the contributions of mast cells, T cells and many other cell types, the relative importance of these potential effector cells probably varying depending on the individual circumstances.

CHRONIC ALLERGIC INFLAMMATION

In patients with chronic atopic diseases, including allergic asthma, allergic rhinitis and atopic dermatitis, the sites of pathology contain complex inflammatory infiltrates, including monocytes, macrophages, eosinophils, neutrophils, mast cells, basophils and T cells, especially those that produce the Th2-type pattern of cytokines that can promote allergic responses. It is likely that all of these participants significantly influence the course of these allergic disorders and, in the aggregate, contribute to the development of the pathology associated with these conditions. Although the recruitment and function of some of these leukocytes can be regulated by mechanisms that are largely independent of the activity of mast cells and basophils, recent findings suggest that mast cell and basophil products may play a larger role in the chronic manifestations of allergic inflammation than was previously supposed.

IgE-dependent activation induces mast cells to release TNF and a broad panel of other cytokines, chemokines and growth factors.¹⁻³ Upon appropriate activation, basophils produce IL-4 and IL-13.^{1-3, 15} Such cytokines have the potential to influence many aspects of the pathophysiology at sites of allergic diseases, including some of the chronic changes (e.g., fibrosis, enhanced mucus production) associated with these disorders.^{1-3, 7, 13, 16} Given that mast cell degranulation results in the local release of proteoglycans that are able to bind a variety of growth factors, FcεRI-mediated mast cell activation may also regulate the function, concentration and spatial distribution of cytokines and growth factors, whether derived from mast cells or other sources, within the tissue microenvironment. In other words, the traditional concept of the self-limited allergic reaction, which was thought to reflect the release of mast cell mediators whose biologic half-lives were measured in minutes or hours, must now be recognized as incomplete. Indeed, the complex and prolonged consequences of cytokine expression, together with the potential long-term effects of some of the cells' other mediators, suggest that mast cell activation can contribute importantly to many of the chronic features of allergic diseases and other disorders associated with mast cell activation.^{1-3, 7, 13, 16} Many other factors probably also contribute to the chronicity of allergic inflammation. These

include prolonged or repeated exposure to relevant allergens, and perhaps the diminished threshold for mast cell activation observed *in vivo* after even a single antigenic challenge.

■ MAST CELLS IN DISEASE AND HOST DEFENSE ■

ASTHMA

Approximately 80–90% of individuals who develop asthma before the age of 30 have an allergic component to the disease. Several lines of evidence indicate that mast cells contribute significantly to the initiation and maintenance of the pathology of allergic asthma (Chapters 39 and 40).^{1–3, 7, 13, 16} In patients with allergic asthma, evidence of mast cell degranulation is provided by elevated levels of histamine and tryptase in the bronchoalveolar lavage fluid of those with moderately symptomatic asthma, and in bronchoalveolar lavage fluids after endobronchial allergen challenge.^{7, 13}

There is growing agreement that the local elaboration of multiple cytokines, chemokines and growth factors, by mast cells and many other cell types, contributes importantly to the pathophysiology of asthma. Evidence includes the extended time course of release observed for some of these mast cell-derived products, the potent biological activities of such molecules, and the amplification and prolongation of the response achieved by the recruitment of additional effector cell types, each capable of contributing additional mediators to the inflammatory response. Mast cells have been proved to contribute to multiple features of asthma in certain mouse 'models' of the disorder, including allergen-induced bronchial constriction and hyperactivity to metacholine, eosinophil and T-cell infiltration, lung collagen deposition, and increased numbers of epithelial goblet cells and proliferating cells in the airway epithelium.^{2, 16} TNF may be especially important in these reactions, as this cytokine can be produced by both mast cells and eosinophils and can augment T-cell proliferation and cytokine production and enhance nonspecific bronchial hyperresponsiveness, as well as mediating many other proinflammatory effects.^{2, 16} However, many cells other than mast cells, such as eosinophils and lymphocytes, as well as structural cells in the lungs such as epithelial cells, fibroblasts and smooth muscle cells, also represent a potentially important source of cytokines, chemokines and growth factors in the chronic allergic inflammation of allergic asthma.^{2, 7, 13, 16} Moreover, mast cell and basophil mediators other than cytokines can also significantly influence disease pathophysiology. Clinical and *in vitro* studies indicate that LTC₄ and its peptidolytic derivatives LTD₄ and LTE₄, derived from mast cells, basophils and other sources, can contribute importantly to disease manifestations in many subjects with atopic asthma.^{7, 13}

PARASITIC DISEASES

IgE-associated allergic disorders are not thought to confer any benefit to the host, and may cause significant pathology or death. What then is the selective advantage of IgE-associated immune responses? Several lines of evidence suggest that mast cells and basophils represent important components of host defense against parasites (Chapters 29 and 46).

Parasitic infections often induce strong primary and secondary IgE responses, with some of the IgE being specific for parasite antigens. Parasite infections are also associated with increased levels of circulating

basophils and eosinophils, and markedly increased serum levels of IgE. This leads to enhanced expression of FcεRI on basophils and mast cells. There are also increased numbers of mast cells at sites of parasitic infection. However, it has been difficult to prove that individual components of this IgE-associated immune response to helminths are truly essential for the expression of protective host immunity to the parasite.

Studies in *Kit*^{W/W^{-v}} and congenic normal mice have documented increased numbers of mast cells at sites of parasite entry in the wild-type mice, and a delayed clearance of the parasite in *Kit*^{W/W^{-v}} mice that lack mast cells. However, expulsion of the parasite did eventually occur even in the absence of mast cells. *Kit*^{W/W^{-v}} mast cell-deficient mice which are also devoid of IL-3 exhibit a striking impairment in their ability to expel a primary infection with the nematode *Strongyloides venezuelensis* (Sv).^{2, 3} In the guinea pig, basophils appear to be required for the expression of immune resistance to cutaneous feeding by larval *Amblyomma americanum* ticks, whereas the expression of IgE-dependent immune resistance to the cutaneous feeding by larval *Haemaphysalis longicornis* ticks in mice is dependent on mast cells.³ These data, as well as many other lines of evidence, suggest that mast cells and basophils may provide similar or overlapping effector functions in parasite immunity, with the relative contributions of one or the other cell type varying according to such factors as the species of the parasite, the specific host and the site of infection. Given the importance of maintaining effective immune resistance to helminth parasites, it is perhaps not surprising that the responses remain largely intact despite the loss of a single effector component, such as IgE or mast cells.

MAST CELLS IN INNATE IMMUNITY

Mast cells may contribute significantly to several aspects of host defense during innate immune responses to bacterial infection. Mast cell knock-in mice were used to show that mast cells can represent a central component of host defense against certain bacterial infections, and that the recruitment of circulating leukocytes with bactericidal properties is dependent on mast cells.^{2, 3, 14, 16} TNF is one important element of this response.^{2, 3, 14, 16} Certain bacterial products – including LPS and other ligands of TLRs – also directly induce the release of some mast cell products.^{7, 14}

Pathogens can also activate mast cells indirectly via activation of the complement system.^{3, 14} Mast cell function in such settings can reflect the interaction between products of complement activation and complement receptors on mast cells and/or the response of mast cells to products of other cells that have been activated by complement-dependent mechanisms.³ Clearly, a lack of mast cells can impair the effectiveness of some innate immune responses, at least in mice.

OTHER DISEASES

Mast cells or basophils or their products have been implicated in a bewildering variety of diseases not thought to be associated with an IgE response (e.g., scleroderma, pulmonary fibrosis of diverse origins, inflammatory bowel disease and peptic ulcer disease), as well as in angiogenesis, adaptive immune responses, protective responses to toxic agents, and reparative responses such as wound healing.^{1–3, 7, 16} Recent data implicate mast cells in the pathogenesis of experimental allergic encephalomyelitis (an animal model of multiple sclerosis) and rheumatoid arthritis.³ However, many of the roles proposed for mast cells or basophils in nonimmunological diseases, adaptive responses or tissue remodeling have not been evaluated using mast cell knock-in mice

or other genetic approaches. Accordingly, the actual importance of the mast cell or the basophil in many of these settings remains to be determined.

MASTOCYTOSIS

Mastocytosis is a heterogeneous disorder associated with the accumulation of mast cells in the skin, bone marrow, gastrointestinal tract, liver, spleen, and lymph nodes. Its true prevalence is unknown. The incidence has been estimated between three and seven new patients per million.²¹ Mastocytosis can present at any age. The onset of two-thirds of all cases is during childhood, mostly during the first 2 years of life.²² A second peak of onset occurs in the late third to early fourth decades. Although most cases are sporadic, approximately 50 cases of familial mastocytosis have been described.

DESCRIPTION AND NATURAL HISTORY

The clinical signs and symptoms of disease observed in patients with mastocytosis are largely explained by tissue mast cell hyperplasia and an excess production of mast cell mediators (Fig. 22.4). The skin is involved in most cases, but mastocytosis does occur without visible skin manifestations. Internal organs can also be affected and constitutional symptoms can be present. The term 'systemic mastocytosis' has been used to categorize patients in whom increased numbers of mast cells are found in organ systems other than the skin.

Adults and children exhibit important differences in clinical presentation, pathogenesis, and prognosis. Whereas mastocytosis in childhood tends to be self-limited and to involve only the skin, the course in patients with adult-onset disease is usually prolonged and includes systemic involvement. Associated hematologic disorders exist or develop in up to 20–30% of adult patients.²³

CUTANEOUS LESIONS

More than 90% of all patients with mastocytosis initially present with hyperpigmented skin lesions (maculopapular cutaneous mastocytosis [MPCM] or urticaria pigmentosa [UP]). These lesions are disseminated

brownish-red macules or slightly elevated papules that may urticate spontaneously or after trauma. This reaction elicited in lesional skin after stroking or rubbing is referred to as Darier's sign. In children, the lesions tend to be well demarcated, whereas in adults they become confluent and may form raised nodules or plaques (Fig. 22.5 A, B).²⁴ Although lesions may involve all sites of the integument, including mucous membranes, the trunk and proximal extremities typically have the highest density of lesions.

Mastocytosis has two additional cutaneous manifestations: solitary mastocytoma, a flat or mildly elevated, and well demarcated, solitary

Fig. 22.4 Clinical manifestations of mastocytosis.

CLINICAL PEARLS

COMPARISON OF CHILDHOOD AND ADULT MASTOCYTOSIS

	Childhood	Adult
>> Etiology	Some with activating <i>c-kit</i> mutations Others unknown	Activating <i>c-kit</i> mutations SCF overproduction (?)
>> Skin involvement	Usually	Variable
>> Cutaneous patterns	Urticaria pigmentosa Mastocytoma Diffuse cutaneous mastocytosis	Urticaria pigmentosa
>> Systemic involvement	Unusual	Common
>> Course	≥50% resolution in adolescence	No resolution
>> Prognosis	Good in most cases	Depends on category

yellowish red-brown lesion, typically 2–5 cm in diameter, that occurs in infants and children, and diffuse cutaneous mastocytosis (DCM). Diffuse cutaneous mastocytosis is a rare disorder that presents in infants in the first year of life. It may involve the entire integument (erythrodermic mastocytosis). DCM presents with edema and doughy thickening of the skin. Serious systemic complications may occur, including hypotension and gastrointestinal hemorrhage, and are in part attributed to high levels of circulating mast cell-derived mediators, including histamine.

Infants and young children with mastocytosis in the skin sometimes exhibit blister formation. Blisters can form spontaneously, or in response to infection or immunization. A biopsy from a mastocytosis skin lesion typically shows increased numbers of normal-looking mast cells in the papillary dermis (Fig. 22.5C).

BONE MARROW AND HEMATOLOGIC INVOLVEMENT

Eighty percent or more of adults with systemic mastocytosis show focal to diffuse collections of spindle-shaped mast cells in the bone marrow (Fig. 22.5D). Fibrotic lesions may develop. Patients also may have a definable hematologic disorder such as a myelodysplastic syndrome, myeloproliferative disorder, acute leukemia, or a malignant lymphoma.²³ Anemia may occur in approximately one-third, and thrombocytopenia and eosinophilia in up to 25%, of all adult patients with mastocytosis.²⁵

Up to 70% of patients with mastocytosis have radiologic abnormalities of bone, partially attributed to the mast cell infiltrates within the bone marrow. Approximately one in three to one in four mastocytosis patients have associated musculoskeletal to fibromyalgia-like pain. Osteoporosis, osteopenia, sclerosis, cystic lesions and, in severe disease, pathologic fractures may occur. The long bones, pelvis, ribs, skull, and vertebrae are the most common sites of skeletal involvement.

MAST CELL MEDIATOR-INDUCED SYMPTOMS

Flushing, shortness of breath, palpitations, nausea and diarrhea, hypotension and occasionally syncope are sometimes experienced by patients with mastocytosis and are believed to result from an excess release of mast cell mediators.²⁶ Patients may describe recurrent episodes with a combination of these symptoms. Such episodes typically last for 30 minutes. Lethargy and fatigue lasting several hours may follow. The frequency and severity of symptoms cannot be predicted by the degree of organ involvement, although such symptoms are considerably more frequent with systemic disease. Systemic episodes occur spontaneously, or they can be provoked in some individuals by stimuli such as hymenoptera insect stings, aspirin and other NSAIDs, opiates (including morphine and its derivatives), muscle relaxants, ethanol, allergies to inhalants or foods, contrast media, surgery or endoscopy, infection (bacteria, viruses, others), and certain physical stimuli such as friction, heat or exercise.

Severe or protracted anaphylaxis may occur in patients with extensive disease, and even fatal reactions have been described. Patients with mastocytosis, however, are not more likely to suffer from allergic diseases. Nevertheless, reactions may be more severe in allergic patients with mastocytosis because of an expanded effector cell population. For example, patients with mastocytosis may develop life-threatening anaphylaxis after hymenoptera stings, during the course of insect venom hyposensitization, or after being administered iodinated contrast materials.²⁷

Involvement of the gastrointestinal (GI) tract is common in patients with systemic mastocytosis. Abdominal pain is the most common symptom, followed by nausea, diarrhea, and vomiting. 56% of the patients characterized their pain as dyspeptic in nature, 44% as nondyspeptic; 25% of these patients indicated that both types of pain were present.²⁸ Diarrhea and malabsorption occurred in 63% and 31% of patients with systemic mastocytosis, respectively. Diarrhea is not generally related to gastric hypersecretion and was attributed to altered intestinal secretion, structural mucosal abnormalities, and hypermotility. Associated malabsorption is usually mild and not clinically important.

OTHER MANIFESTATIONS

Liver disease is common in patients with mastocytosis.²⁸ Hepatomegaly was reported in 24%, and elevated levels of liver enzymes in 54% in one series of 41 patients. Mast cell infiltrates were frequently found in liver biopsies. However, severe liver disease was uncommon, except in those with aggressive disease. In these patients, fibrosis, cirrhosis, ascites, and portal hypertension were reported to be more frequent.

The spleen appears to be involved in 40–50% of patients with systemic disease. Splenomegaly is more pronounced in those with aggressive disease. Mast cell infiltrates are observed in biopsy specimens. Peripheral lymphadenopathy has been reported in 26–56% of patients with mastocytosis. Adenopathy is more common in patients with associated hematologic disorders and more aggressive disease.

Patients with mastocytosis sometimes report neuropsychiatric problems. Altered neurological function such as poor attention, irritability, impaired memory, personality change and depression have been observed.

PROGNOSIS AND CLASSIFICATION

The clinical course varies from asymptomatic with normal life expectancy to highly aggressive, and depends on the variant of disease. The WHO classification defines seven variants (Table 22.3).²⁹ The term ‘systemic mastocytosis’ (SM) has been used to categorize patients in whom increased numbers of mast cells are found in organ systems other than the skin. It is defined in the WHO classification by a major criterion of multifocal mast cell infiltrates in the bone marrow or in other extracutaneous organ(s) (>15 mast cells per aggregate detected by tryptase immunohistochemistry) and four minor criteria: 25% or more of mast cells in biopsy sections of bone marrow or other extracutaneous organs show a spindle-shaped or abnormal morphology, or more than 25% of all mast cells in bone marrow aspirate smears are immature or atypical mast cells; detection of a *c-kit* mutation at codon 816 in bone marrow, blood or other extracutaneous organ(s); mast cells in the bone

Aggressive systemic mastocytosis
Mast cell leukemia
Mast cell sarcoma
Extracutaneous mastocytoma

Fig. 22.5 Cutaneous mastocytosis and histopathology. Urticaria pigmentosa is the most common form of cutaneous mastocytosis. In childhood, lesions are disseminated and consist of well-demarcated hyperpigmented macules (e.g. arrows) (**A**). In adults, lesions may be numerous with less well-demarcated brownish-red macules and papules (**B**). Histopathology of cutaneous mastocytosis shows a slight perivascular mononuclear cell infiltrate with mast cells containing abundant tryptase immunoreactive cytoplasmic granules is seen in the papillary dermis (antitryptase, AA1 clone, Dako; original magnification $\sim \times 400$) (**C**). Bone marrow pathology of indolent mastocytosis is characterized by paratrabecular lymphoid nodule containing small, well-differentiated lymphoid cells around substantial numbers of fusiform cells with prominent granules in the tryptase stain (arrow) (antitryptase, AA1 clone, Dako; original magnification $\sim \times 250$) (**D**). (Courtesy of Dr Cem Akin.)

marrow or in another extracutaneous organ co-express CD117 (KIT) with CD2 and/or CD25; and serum total tryptase that is persistently greater than 20 ng/mL. If at least one major and one minor, or at least three minor criteria for SM are fulfilled, the diagnosis is SM. Criteria defining the mast cell burden, involvement of non-mast cell lineages and aggressiveness of disease are applied to subclassify SM in subvariants.²⁹

Particularly in children, mastocytosis of the skin (cutaneous mastocytosis) may be the only manifestation, and about 50% of such cases resolve during puberty.³⁰ Most adults fall into the indolent systemic mastocytosis category and the disease tends to remain stable over many years.³¹ Progression of the skin involvement may occur, but evolution of disease into more severe forms is uncommon.

Patients in the other categories may have a less favorable prognosis and some may experience a rapid progression.²³ Patients in these categories are less likely to exhibit involvement of the skin. Factors influencing the clinical course are the associated hematologic abnormalities and the rapidity of the increase in mast cell numbers (especially in aggressive mastocytosis and mast cell leukemia).

Mast cell leukemia is the rarest form and has the most fulminant behavior. Mast cell leukemia is diagnosed when bone marrow aspirate smears show 20% or more mast cells and 10% or more of the peripheral blood nucleated cells are mast cells. Survival of those with mast cell leukemia is generally less than 1 year.

ETIOLOGY AND PATHOGENESIS

The most important survival/growth factor for mast cells is the KIT ligand SCF. At least in adults, it is thought that one initial event that can result in mastocytosis is an activating mutation in *c-kit*, the gene for KIT.³² KIT, a transmembrane tyrosine kinase receptor encoded by the pro-oncogene *c-kit*, is expressed on mast cells, melanocytes, hematopoietic stem cells, interstitial cells of Cajal and germ cell lineages. Ligation of KIT by SCF promotes dimerization of the receptor and subsequently induces intrinsic tyrosine kinase activation. The resulting phosphorylated tyrosine residues serve as docking sites for intracellular downstream signaling pathways leading to cell proliferation and activation.

In more than 90% of adult patients with SM neoplastic mast cells exhibit a somatic 'autoactivating' mutation at codon 816 of *c-kit*. The most commonly detected mutant is Asp816Val, which has been identified not only in the bone marrow, but also in the skin and spleen in some patients. Most mutations are somatic: only rare germline mutations have been reported in cases of familial mastocytosis. These findings support the conclusion that the disease is clonal, and suggest that mastocytosis could be regarded as a clonal rather than a hyperproliferative disorder. The reason(s) for the different behavior of indolent versus aggressive variants of mastocytosis, however, remain(s) unknown. Patients with hypereosinophilia and high numbers of mast cells on the basis of a FIP1L1-PDGFR α fusion have been described.³³

The Asp816Val *c-kit* mutation has also been described in biopsies of lesional skin of children with more severe forms of mastocytosis. However, it appears overall to be unusual in lesional biopsies of children with typical MPCM. Several additional *c-kit* mutations have been detected in some children and adults, but their clinical relevance is less clear. These findings raise the possibility that in many children mastocytosis has a different basis from that in most adults, and this could provide an explanation for the generally more benign course of some cases of childhood UP.

DIAGNOSIS

Most patients with mastocytosis present with characteristic cutaneous lesions that support the diagnosis. Histological examination of the skin should be performed at initial presentation. Mast cells within skin biopsies are identified using toluidine blue or Giemsa stains, or by immunohistochemistry using antibodies to mast cell tryptase. A 15–20-fold increase in mast cell numbers has been reported in lesions of UP, but the increase may be less pronounced.²⁶ However, a two- to fourfold increase in mast cell numbers has been observed in unrelated conditions, including idiopathic anaphylaxis, flushing, chronic urticaria, and eczema.

Biochemical demonstration of elevated serum levels of total mast cell tryptase (>20 ng/mL) supports the diagnosis of SM, whereas in cutaneous mastocytosis tryptase levels may be normal.³⁴ In addition, elevation in urinary histamine and its metabolites may be observed in SM. However, mast cell tryptase and histamine can also be elevated in association with acute exacerbations of allergic diseases, including anaphylaxis, and, in the case of tryptase, clonal myeloid disorders. Therefore such elevations in total tryptase, in isolation, are not diagnostic of mastocytosis.

In patients with elevated serum total tryptase, bone marrow biopsy and aspiration should be considered, particularly in adults. A bone marrow biopsy is also useful for staging the disease by excluding associated hematologic abnormalities. In patients with an associated hematologic disorder, identification of mast cells in the bone marrow may be difficult if the mast cells are dysplastic and when mast cell granules are more coarse than normal, or are even absent.³⁵ The most accurate stain for the detection of mast cells in mastocytosis is an immunohistochemical stain with antibody to mast cell tryptase. Identifying, by flow cytometry of bone marrow aspirates or by immunohistochemical analysis of bone marrow biopsies, the co-expression of CD2 and/or CD25 in CD117 (KIT)-positive mast cells has been considered the most sensitive and specific method to support the diagnosis of SM in the bone marrow.³⁶

Although it can be performed on blood or peripheral tissues, *c-kit* mutation analysis is best performed on bone marrow, and particularly on sorted malignant mast cells to increase sensitivity. Inability to identify the presence of a point mutation at codon 817 in *c-kit* does not eliminate the possibility that cells bearing this mutation are present, in that the malignant clone may not have expanded to sufficient cell numbers to allow the detection of a mutation.

In patients with SM, the size of the liver and spleen should be measured by ultrasound or CT, and bone density should be measured by the DXA method to evaluate for osteoporosis. SM is classified into one of the more aggressive variants of disease when there is bone marrow involvement of non-mast cell lineages, organ dysfunction and/or a high mast cell burden.

Further studies, such as gastrointestinal endoscopy or biopsy to obtain tissue specimens from the liver, spleen, gastrointestinal tract or lymph nodes, are usually considered only when these organs are suspected to be involved and a biopsy would yield clinically useful information. A physical examination, serum tryptase determination and a complete blood count should be performed at yearly intervals in patients with indolent stable SM.

THERAPY

There currently is no cure for cutaneous or systemic mastocytosis.³⁷ Treatment is symptomatic and is tailored to the individual. Prominent mast cell mediator-induced symptoms include hypotension, gastric hypersecretion, abdominal pain, and pruritus. Aggressive forms of therapy are not indicated in patients with indolent mastocytosis, as this disorder has a favorable prognosis. In patients with aggressive disease or associated hematologic disorders, treatment is a therapeutic challenge.

THERAPY OF CUTANEOUS AND INDOLENT DISEASE

In patients with indolent disease, management includes reassurance, avoidance of exacerbating factors, and treatment that offers symptomatic relief. Information about the nature of the disease, an explanation

of expected symptoms, and discussion of prognosis will address the most common concerns of patients with mastocytosis. Factors known to provoke episodes of flushing and hypotension should be reviewed with the patient and avoided. Patients with mastocytosis and hymenoptera venom exposure are at risk for severe anaphylaxis. Epinephrine is the drug of choice for anaphylaxis and should be kept available by patients at risk at all times. Immediate self-administration during anaphylaxis may be life-saving. Insect venom immunotherapy, as well as premedication with antihistamines and corticosteroids prior to general anesthesia, should be seriously considered.

Nonsedating H₁ antihistamines are the agents of choice for pruritus and urtication. For prophylaxis of recurrent episodes of anaphylaxis, antihistamines should be administered daily. For some patients, classic sedating H₁ blockers, such as hydroxyzine or diphenhydramine, seem to be more effective. The addition of an H₂-receptor antagonist is also an option. Gastric acid hypersecretion, peptic ulcer disease, and reflux esophagitis are managed with H₂-receptor blockers and proton pump inhibitors. Cromolyn sodium may be used, particularly for gastrointestinal symptoms. Anticholinergics are an option for control of diarrhea. Systemic corticosteroids are used in cases of malabsorption or ascites. Calcium, vitamin D and bisphosphonates are the drugs of choice for osteoporosis.

Application of topical corticosteroids under occlusion or topical PUVA (psoralen plus UVA radiation) treatment may be considered in patients with cutaneous mastocytosis. Both are effective in reducing pruritus and urtication, but relapse typically occurs a few months after therapy is discontinued. Patients also report a diminution or decrease in intensity of skin lesions in the summer and after repeated exposure to natural sunlight. The benefits of these forms of therapy have to be weighed against the potential for inducing cutaneous malignancies associated with long-term UV radiation.

THERAPEUTIC PRINCIPLES

Avoidance of exacerbating factors

Therapy of cutaneous and indolent disease

- >> H₁ antihistamines
- >> H₂ antihistamines
- >> Cromolyn sodium
- >> Anticholinergics
- >> Systemic glucocorticoids (malabsorption)
- >> Epinephrine (hypotension)
- >> Ultraviolet radiation (PUVA, UVA₁)
- >> Topical glucocorticosteroids (mastocytoma)

Therapy of aggressive disease and associated hematologic disorders

- >> Interferon- α_{2b}
- >> Cladribine
- >> Chemotherapy
- >> Imatinib (in mutations other than in codon 816)
- >> Experimental: new tyrosine kinase inhibitors, bone marrow transplantation

THERAPY OF AGGRESSIVE DISEASE AND ASSOCIATED HEMATOLOGIC DISORDERS

Patients with mastocytosis and an associated hematologic disorder should be managed using therapy appropriate for the associated disorder. Chemotherapy has not been shown to produce remission, or to prolong survival, in mast cell leukemia, and is not indicated in indolent mastocytosis, as it may lead to bone marrow suppression without improving the symptoms of mastocytosis. A partial response to interferon- α_{2b} has been reported in patients with aggressive mast cell disease. However, other reports of its value have been mixed.³⁸ Cladribine (2-chlorodeoxyadenosine) has been reported to reduce the mast cell burden and may be considered in aggressive mastocytosis.³⁹

New therapeutic approaches should target neoplastic mast cells. The tyrosine kinase inhibitor imatinib is not generally considered to be indicated in patients with typical Asp 816Val mutations in KIT, as steric conformations of the receptor interfere with the action of the drug in this setting.⁴⁰ However, the drug has been reported to reduce mast cell load and symptoms in patients with mutations in other c-KIT exons. Other tyrosine kinase inhibitors have been developed which may also inhibit mutations in codon 816, and some of these are currently in clinical trials. Therapies that target markers such as CD25 expressed on mast cells are also currently under investigation. Bone marrow transplantation may evolve as an option, although results to date have been disappointing.

ACKNOWLEDGMENTS

We thank Dr Ann M. Dvorak for providing the electron micrographs and Drs. John J. Costa and Jochen Wedemeyer for their contributions to the first edition of this chapter. Some of the work reviewed in this chapter was supported by United States Public Health Service grants AI 23990, CA72074 and HL67674 (Project 2), by Deutsche Forschungsgemeinschaft grant ME2668/1-1, by the Intramural Research Program of NIAID and/or by AMGEN Inc.; Dr Galli consults for AMGEN Inc. under terms that are in accord with Stanford University conflict-of-interest guidelines.

Eosinophils and eosinophilia

Peter F. Weller

23

Eosinophils are terminally differentiated, bone marrow-derived granulocytes that normally circulate in the blood in low numbers and tend to localize in those tissues with mucosal epithelial surfaces. Increased blood or tissue eosinophils occur with helminth parasite infections as well as with allergic diseases and a variety of other, often idiopathic conditions. Conventionally the major focus on eosinophils has been delineating the 'effector' functions of these end-stage granulocytes, including what roles these cells play as helminthotoxic effector cells and the contribution they make to the immunopathogenesis of allergic diseases. More recent findings indicate that eosinophil functions are considerably more extensive.¹⁻⁴ Eosinophils contain stores of multiple pre-formed cytokines, engage in cognate cell-cell interactions with other cell types, including lymphocytes, and have a role in varied host immune and inflammatory responses not conventionally marked by quantitatively extensive eosinophil infiltration.

■ PRODUCTION AND DISTRIBUTION OF EOSINOPHILS ■

EOSINOPHILOPOIESIS

The development of eosinophils in the bone marrow can be elicited by three cytokines. Granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin (IL)-3 and IL-5 each promote eosinophilopoiesis. In contrast to IL-3 and GM-CSF, which also promote the development of other lineages, IL-5 uniquely promotes the development and terminal differentiation of eosinophils. Although IL-5 is produced by CD8 T cells, NK cells, and other leukocytes, including eosinophils themselves, IL-5 is a defining cytokine product of Th2 CD4 T cells. The production of IL-5 by Th2 lymphocytes accounts for the eosinophilia accompanying Th2 cell-mediated immune responses characteristic of helminth infections and allergic diseases. Increases in blood IL-5 have been detectable in some, but not all, patients with eosinophilias of varying causes, including some with hypereosinophilic syndromes and parasitic infections.

Eosinophilopoiesis develops over about a week. Retained in the marrow is a pool of mature eosinophils. IL-5, alone and in concert with the

chemokine eotaxin, rapidly releases this pool of mature eosinophils into the circulation to acutely increase blood eosinophilia and facilitate recruitment of eosinophils to sites of inflammation.² Blood eosinophils circulate with a half-life of about 8–18 hours. Eosinophils leave the circulation and localize in tissues, especially those with mucosal interfaces with the outside world, such as the respiratory, gastrointestinal and lower genitourinary tracts. Although the mechanisms governing this homing of eosinophils to mucosal tissues are not fully known, the chemokine eotaxin is involved in the homing of eosinophils to the gastrointestinal, but not the respiratory, tract.² Eosinophils live longer than neutrophils and probably persist in tissues for several weeks. They are principally tissue-dwelling cells: as demonstrated in rodents, for every eosinophil present in the circulation there are 300–500 in the tissues.

EOSINOPHIL ADHERENCE MECHANISMS

The transit of eosinophils from the marrow, through the circulation and into tissues is governed in part by multiple adherence molecules expressed on eosinophils (Fig. 23.1).⁵ As for other leukocytes, recruitment of eosinophils into tissue sites of inflammation utilizes combinatorial interactions involving specific adhesion molecules (via their expression and altered affinity states) that mediate cellular interactions with the

KEY CONCEPTS

ACTIONS OF EOSINOPHILOPOIETIC CYTOKINES IL-3, GM-CSF, IL-5

- Promote eosinophil development and maturation in the marrow.
- Release a pool of matured eosinophils from the marrow.
- Sustain the viability and antagonize apoptosis of mature eosinophils, enhance multiple effector responses of mature eosinophils

Fig. 23.1 Adherence mechanisms utilized by human eosinophils to bind to vascular endothelial cells and the extracellular matrix molecules. ICAM, intracellular adhesion molecule; VCAM, vascular cell adhesion molecule; MadCAM, mucosal addressin cell adhesion molecule; VLA, very late activation antigen.

vascular endothelium and actions of chemoattractant molecules. Eosinophils express several adhesion molecules broadly shared with other leukocytes that mediate their initial rolling and subsequent adherence to endothelial cells. Similar to neutrophils, eosinophils can adhere via CD11/CD18 heterodimeric β_2 -integrins to the intercellular adhesion molecules ICAM-1 and ICAM-2. Likewise, specific sialoglycoproteins mediate adherence between eosinophils and endothelial E- and P-selectins. Unlike neutrophils, but similar to lymphocytes, eosinophils are able to bind to vascular cell adhesion molecule-1 (VCAM-1). Eosinophils express two α_4 -integrins, very late activation antigen-4 (VLA-4, $\alpha_4\beta_1$) and $\alpha_4\beta_7$, that bind to VCAM-1. Moreover, $\alpha_4\beta_7$ binds to the mucosal addressin, mucosal addressin cell adhesion molecule (MadCAM). The β_2 -integrin, $\alpha\delta\beta_2$, which binds ICAM-3 and is expressed on other leukocytes, is an additional integrin that mediates eosinophil adhesion to VCAM-1. Enhanced expression of VCAM-1 on the vascular endothelium, as elicitable by IL-4 or IL-13 stimulation, may contribute to the localization of eosinophils in some tissue sites of inflammation.

In addition to mediating interactions with the endothelium, eosinophil adherence molecules, by their interactions with extracellular matrix components, modulate the activity of eosinophils that have exited the bloodstream. Eosinophil VLA-6, $\alpha_6\beta_1$, binds laminin. Both $\alpha_4\beta_1$ and $\alpha_4\beta_7$ interact with specific domains of tissue fibronectin, and these interactions can enhance eosinophil functional responses. Eosinophils express CD44 (PGP-1), which binds hyaluronic acid. Siglec-8, a sialic acid-binding immunoglobulin-like lectin, is expressed on eosinophils and binds sialoglycoconjugates.

EOSINOPHIL CHEMOATTRACTANTS

Mobilization of eosinophils into tissues is governed by receptor-mediated chemoattractant stimuli. Chemoattractants promote the directed migration of eosinophils and may enhance the adhesion of eosinophils to vascular endothelium and their subsequent migration through the endothelium. Many compounds have been identified as

eosinophil chemoattractants, including humoral immune mediators, such as platelet-activating factor (PAF) and the complement anaphylatoxins C5a and C3a; certain cytokines; and several chemokines, most notably the eotaxins. None of these is specific solely for eosinophils, but eotaxin, eotaxin-2 and eotaxin-3 exhibit the most restricted specificity.² Eotaxins signal through CCR3 chemokine receptors that are expressed on eosinophils as well as basophils, some Th2 cells and some mast cells. Thus, recruitment of eosinophils to sites of immunologic reactions is governed by their response to chemoattractants that facilitate intravascular emigration and direct migration of extravascular eosinophils, as well as by the functional states of eosinophil adherence molecules and the differential expression of endothelial cell adherence ligands.

■ STRUCTURE OF EOSINOPHILS ■

Human eosinophils, unlike neutrophils, usually have a bilobed nucleus (Fig. 23.2). Defining attributes of eosinophils are their large, cytoplasmic 'specific' granules that are morphologically distinct because of their unique content of crystalloid cores. Crystalloid cores are recognizable by transmission electron microscopy and usually appear electron dense (Fig. 23.2). The cores and surrounding matrices of specific granules contain cationic proteins that account for the tinctorial staining of granules with eosin. Eosinophils at sites of inflammation can exhibit morphologic changes in their specific granules, including loss of either matrix or core components from within intact granules, compatible with the extracellular release of granule constituents.

Lipid bodies, cytoplasmic structures distinct from granules (Fig. 23.2), are roughly globular in shape and range in size from minute to the size of specific granules. Lipid bodies are dissolved by common alcohol-based hematologic stains, but with osmium fixation are preserved and stain darkly. Lipid bodies lack a delimiting membrane, but contain internal membranes that are often obscured by overlying lipid. Lipid bodies are

Fig. 23.2 Transmission electron micrograph of a human eosinophil. The numerous cytoplasmic specific granules (arrow heads) contain the electron-dense crystalline cores that are unique to eosinophils. In addition, lipid bodies (arrows) are visible as globular, uniformly dark structures. (Original magnification $\times 11,180$.) (Courtesy of Dr Ann M. Dvorak, Israel Deaconess Medical Center, Harvard Medical School, Boston.)

found in neutrophils and other cells, especially in association with inflammation; but eosinophils typically contain more lipid bodies than neutrophils. Lipid body formation in eosinophils is rapidly inducible within minutes. In eosinophils, key enzymes involved in eicosanoid formation, including prostaglandin H synthase, the 5- and 15-lipoxygenases and leukotriene (LT) C_4 synthase, localize at lipid bodies; and lipid bodies are sites of eicosanoid synthesis.⁶

CELL SURFACE RECEPTORS AND PROTEINS

Eosinophil receptors for immunoglobulins include those for IgG, IgE, and IgA. The receptor for IgG on eosinophils is principally the low-affinity $Fc\gamma RII$ (CD32), whereas neutrophils have $Fc\gamma RII$ and $Fc\gamma RIII$ (CD16). Exposure of eosinophils to interferon (IFN)- γ elicits expression of a phosphatidylinositol-linked form of CD16 on eosinophils, and CD16 may be expressed on eosinophils from some patients with eosinophilic disorders.

Eosinophil IgE receptors include the high-affinity IgE receptor $Fc\epsilon RI$, typically found on basophils and mast cells, as well as $Fc\epsilon RII$, the low-affinity IgE receptor, like CD23 found on lymphocytes, monocytes, and antigen-presenting cells. Although $Fc\epsilon RI$ α chain protein is present within eosinophils, its surface expression can be low or undetectable. Engagement of eosinophil $Fc\epsilon RI$ does not elicit exocytotic degranulation, as it does on basophils and mast cells. $Fc\epsilon RI$ may participate in IgE-mediated antigen uptake by antigen-presenting eosinophils, but the functional roles of eosinophil $Fc\epsilon RI$ remain to be delineated. Eosinophil expression of IgE receptors is notable because IgE levels and eosinophil

numbers frequently increase concomitantly in helminth parasitic infections as well as allergic diseases.

Eosinophils express $Fc\alpha RI$ (CD89), which binds secretory IgA more potently than do other forms of IgA. Engagement of $Fc\alpha RI$ triggers eosinophil release of granule proteins. With the characteristic localization of eosinophils to mucosal surfaces of the respiratory, gastrointestinal, and genitourinary tracts, this IgA receptor enables eosinophils to engage secretory IgA present at these mucosal sites.

Eosinophils have receptors for complement components including C1q (CR1), C3b/C4b (CR1), iC3b (CR3), C3a and C5a. Both C3a and C5a are eosinophil chemoattractants and stimulate the production of oxygen radicals by eosinophils. Eosinophils express several receptors for chemokines. CCR1 is a receptor for MIP-1 α , MCP-3 and RANTES, whereas CCR3 is a receptor for eotaxin, eotaxin-2, eotaxin-3, MCP-3 and RANTES. Eosinophils express CXCR4 and respond to the ligand for this receptor, stromal cell-derived factor-1 α .

Mature eosinophils, like their immature precursors, express receptors for the three cytokines, GM-CSF, IL-3, and IL-5, that promote eosinophilopoiesis and stimulate the functioning of mature eosinophils. In addition, eosinophils have receptors for a broad range of other cytokines, including IL-1 α , IL-2, IL-4, IFN- α and IFN- γ , TNF- α , stem cell factor (*c-kit*) and IL-16 (which signals via CD4 on eosinophils). Thus, eosinophils are subject to stimulation by many cytokines, although little is understood about how many of them affect eosinophil functioning *in vivo*.

Of pertinence to interactions between eosinophils and B and T lymphocytes, eosinophils may express several relevant plasma membrane proteins. Class II MHC proteins, generally absent on blood eosinophils, are induced for expression on eosinophils in sites of inflammation. In addition, eosinophils can express CD40, CD154 (CD40 ligand), CD153 (CD30 ligand), CD28 (B7-2) and CD86.⁷

Eosinophils express receptors for several lipid mediators, including platelet-activating factor (PAF) and leukotriene B_4 (LTB $_4$), which are chemoattractants for eosinophils and stimulate eosinophil degranulation and respiratory burst activity. Eosinophils also have receptors for prostaglandin E_2 and for cysteinyl leukotrienes.

CONSTITUENTS OF EOSINOPHILS

Eosinophil specific granules contain pre-formed proteins that include both specific cationic proteins and stores of diverse cytokines and chemokines.

CATIONIC GRANULE PROTEINS

Eosinophil granule cationic proteins have been extensively studied because of their abundance in the granules and their capacity to exert multiple effects on host cells and microbial targets.⁸ Major basic protein (MBP), named for its quantitative predominance within the granule and its markedly cationic (basic) isoelectric point of about 11, is a 13.8–14 kDa protein. A homolog of MBP that is somewhat smaller (13.4 kDa) and less basic (pI 8.7) has been identified. MBP lacks enzymatic activity and probably exerts its varied effects via its markedly cationic nature.

A second granule protein is eosinophil peroxidase (EPO), an enzyme distinct from neutrophil myeloperoxidase. Cationic EPO (pI 10.8) uses hydrogen peroxide and halide ions to form hypohalous acids, which are

toxic for parasites, bacteria, and tumor and host cells. EPO utilizes bromide in preference to chloride and is even more active with a pseudo-halide, thiocyanate, to generate oxidant products, including hypobromous and hypothiocyaneous acids.

Two additional granule proteins are eosinophil cationic protein (ECP) (18 kDa, pI 10.8) and eosinophil-derived neurotoxin (EDN) (18–19 kDa, pI 8.9). EDN, never demonstrated to be neurotoxic for humans, is so named because, after it is injected intracerebrally into test rabbits, it elicits a characteristic neuropathologic response. Both ECP and EDN are ribonucleases (RNases). EDN expresses 100 times more RNase activity than does ECP, although their toxic effects on bacterial, parasitic and mammalian target cells are apparently unlikely to be due to their RNase catalytic activities.

Within the specific granule, MBP is localized to the crystalloid core, whereas ECP, EDN and EPO are localized in the matrix of the granule around the core (see Fig. 23.1). MBP is also found in low amounts (~3% of eosinophil levels) in basophils, but whether this reflects endocytosis or endogenous synthesis is not known. Uptake of MBP and EPO into mast cells is known to occur via endocytosis. Small amounts of EDN and ECP are present in neutrophils, and as neutrophils contain mRNA transcripts for these, EDN and ECP are likely synthesized by neutrophils. Nevertheless, eosinophils are the dominant source of these four cationic proteins. The properties of these proteins and their numerous biologic effects have been reviewed,⁸ as these proteins have major effects not only in the potential role of eosinophils in host defense against helminthic parasites, but also in contributing to tissue dysfunction and damage in eosinophil-related allergic and other diseases.

CYTOKINES AND CHEMOKINES

Eosinophils are capable of elaborating at least 31 diverse cytokines and chemokines, and studies continue to identify more cytokines released by eosinophils. The potential activities of eosinophil-derived cytokines are extensive. Eosinophil-derived cytokines include those with autocrine growth factor activities for eosinophils and those with a potential role in acute and chronic inflammatory responses. A notable feature of eosinophils as a source of cytokines is that they contain stores of these cytokines pre-formed within eosinophil granules and secretory vesicles.⁹ Thus, in contrast to most lymphocytes, which must be induced to synthesize *de novo* cytokines destined for release, eosinophils can immediately release pre-formed cytokine and chemokine proteins into the surrounding milieu. Although levels of pre-formed cytokines in eosinophils may be lower than those of specifically stimulated lymphocytes, local and rapid release of eosinophil-derived cytokines in tissues could readily induce a response in various adjoining cell types.

Eosinophils synthesize the three growth factor cytokines GM-CSF, IL-3 and IL-5, which promote eosinophil survival, antagonize eosinophil apoptosis, and enhance eosinophil effector responses. Other cytokines elaborated by human eosinophils that may have activities in acute and chronic inflammatory responses include IL-1 α , IL-6, IL-8, IFN- γ , TNF- α and MIP-1 α . Human eosinophils can elaborate other various 'growth' factors, including transforming growth factor (TGF)- α , TGF- β 1, vascular endothelial growth factor, platelet-derived growth factor (PDGF)- β , and heparin-binding epidermal growth factor. These cytokines may have a role in contributing to epithelial hyperplasia and fibrosis, as well as other activities. In addition, eosinophils are recognized as sources of specific cytokines and chemokines capable of stimulating or

inhibiting lymphocyte responses, including IL-2, IL-4, IL-10, IL-12, IL-16, RANTES and TGF- β 1. Of note, eosinophil cytokines include those associated with Th2 (IL-4, IL-5, IL-13), Th1 (IL-12, IFN- γ) and T-regulatory (IL-10, TGF- β) responses, emphasizing the diverse immunoregulatory potentials for eosinophil-secreted cytokines.

■ ACTIVATED EOSINOPHILS ■

A well recognized attribute of eosinophils is that, in conjunction with eosinophilic diseases, some blood and tissue eosinophils may exhibit various alterations indicative that these cells have been 'activated.' These changes include increased metabolic activity, diminished density ('hypodense'), enhanced LTC₄ formation, and morphologic alterations, including cytoplasmic vacuolization, alterations in granule numbers and size, and losses within specific granules of MBP-containing cores or matrices. Activated eosinophils may exhibit enhanced plasma membrane expression of some proteins, including CD69, HLA-DR and CD25.

Features associated with *in vivo* 'activated' eosinophils can be elicited in part by exposing eosinophils to specific stimuli, including GM-CSF, IL-3 and IL-5. In addition, interactions with extracellular matrix components can further contribute to eosinophil activation. Eosinophil 'activation,' however, is not a singularly binary process, and some attributes of activation can be elicited without other attributes by mediators and mechanisms that remain to be delineated.

■ MECHANISMS OF EOSINOPHIL DEGRANULATION ■

As eosinophil granules contain four major cationic proteins and a multitude of pre-formed cytokines and chemokines, the processes by which eosinophils mobilize these granule constituents for their extracellular release are important in understanding the regulated functioning of eosinophils. Unlike mast cells or basophils that undergo acute exocytotic degranulation in response to cross-linking of their high-affinity Fc ϵ receptors, an analogous mechanism to elicit comparable exocytotic degranulation of fluid-phase eosinophils has not been identified. Cross-linking of eosinophil IgG or IgA Fc receptors can stimulate release of eosinophil cationic proteins, but this rapid FcR-mediated acute 'degranulation' process is cytolytic for eosinophils. In contrast, observations of eosinophils on the surfaces of large non-phagocytosable multicellular helminth parasites do provide evidence that eosinophils can degranulate by exocytosis to release granule contents on the surfaces of target parasites.

An alternative means of mobilizing granule contents for secretion that eosinophils utilize is a process of vesicular transport-mediated 'piecemeal' degranulation. Electron microscopic observations of lesional eosinophils provided evidence that eosinophil granule contents were mobilized *in vivo* by selective incorporation into small vesicles that traffic to the cell surface and release these granule contents. By this process, there may be agonist-elicited selective secretion of certain eosinophil-derived cytokines.^{9, 10} Ultrastructural studies have demonstrated that secretory vesicles arise from granules and transport cytokines, such as IL-4.^{11, 12} Insights into the selectivity and mechanisms of differential cytokine secretion have been indicated by finding, at least for IL-4, that a receptor for IL-4 mediates the transport of

IL-4 from granules and within secretory vesicles.¹³ How this process of vesicular transport is regulated and functions to selectively mobilize specific eosinophil granule-derived cytokines or cationic proteins remains under investigation.

In addition to regulated release of granule contents from viable eosinophils, a common, but often overlooked and enigmatic, occurrence is the apparent lysis of eosinophils. Both cutaneous and pulmonary biopsies of eosinophil-associated diseases contain free, extracellular, but still membrane-bound eosinophil granules. The mechanism of cytolysis in such reactions is undefined, but may represent eosinophil apoptosis and occur more commonly than heretofore recognized. Whether this process releases granule-bound proteins is uncertain.

FUNCTIONS OF EOSINOPHILS

Conventional considerations of the roles that eosinophils may play have been guided by quantitative considerations, so that those diseases characteristically marked by more prominent eosinophilia have occasioned the most interest. Thus, studies have focused on the 'effector' roles eosinophils play in host defense against helminth infections and in the immunopathogenesis of allergic and other eosinophilic diseases. Additional roles for eosinophils must be considered in immune or inflammatory responses not conventionally recognized to contain abundant eosinophils.

ROLES IN HOST DEFENSE

Because the host response to infections with multicellular helminth parasites is characteristically associated with eosinophilia, it is often believed that eosinophils evolved to have a role in killing helminths, especially during their larval stages. Indeed, *in vitro* eosinophils can kill numerous helminths, organisms too large to be phagocytosed. Eosinophils adhere to the parasite and deposit eosinophil granule contents onto its surface. Cell products that can contribute to parasite death include MBP, ECP, EDN, and EPO.

As reviewed,¹⁴ the helminthotoxic roles of eosinophils *in vivo* are less certain in humans and experimental rodents. In eosinophil-depleted mice (given neutralizing antibody to IL-5, or with the IL-5 gene deleted), the intensities of primary and secondary infections with some helminths have not been greater than in eosinophilic mice, nor have IL-5 transgenic mice exhibited increased resistance to infection with some helminth species. Moreover, schistosome infections in two lines of eosinophil-ablated mice have shown no differences in measures of infection compared to normal mice.¹⁵ Nevertheless, murine studies need to be interpreted with caution. Some helminth infections elicit Th1-biased responses in mice, which differ from Th2-biased responses in humans or rats. Many experimental infections involve introducing helminth infections that are often host species-restricted into unnatural host mice, in which innate immune responses may be prominent. Natural human infections are usually a consequence of repeated exposures, during which acquired, rather than innate, immunity becomes prominent. Thus, eosinophil functions as helminthotoxic cells *in vivo* remain unclear. Eosinophils might have an alternative function in the host response to helminths, including functioning as antigen-presenting cells.^{15, 16}

ROLES IN DISEASE PATHOGENESIS

The ability of eosinophils to release biologically active lipids as paracrine mediators of inflammation and to release pre-formed cationic and cytokine granule constituents enables them to contribute to the immunopathogenesis of various diseases, including asthma.^{3, 17} Eosinophils form several classes of biologically active lipid. Eosinophils, like other cells, may liberate PAF. The potent, diverse activities of PAF can be mediated either directly or by stimulating other cells to release leukotrienes, prostaglandins, and complement peptides. Stimulated eosinophils also release LTC₄. LTD₄ and LTE₄ are formed from LTC₄ by the sequential enzymatic removal of glutamic acid and glycine from its tripeptide glutathione side chain. LTC₄, and especially LTD₄, has bronchoconstrictor activity, constricts terminal arterioles, dilates venules, and stimulates airway mucus secretion. Thus, eosinophils are a potential source of two major types of mediator lipids, the sulfidopeptide leukotrienes and PAF.

Oxidants released by eosinophils, including superoxide anion, hydroxyl radical, and singlet oxygen, and EPO-catalyzed hypothiocyanous acid and other hypohalous acids, have the potential to damage host tissues.

Released eosinophil granule proteins are immunochemically detectable in fluids, including blood, sputum and synovial fluids, and in tissues, including the respiratory and gastrointestinal tracts, skin, and heart, in association with various eosinophil-related diseases. The eosinophil cationic proteins, including MBP, ECP, and EPO, can damage various cell types. Thus, extracellular release of eosinophil granule proteins, by degranulation or cytolysis of eosinophils, could contribute to local tissue damage by causing dysfunction and damage to adjacent cells.

OTHER EOSINOPHIL FUNCTIONS

Other potential functions for the eosinophil are not fully defined. In addition to the acute release of lipid, peptide and cytokine mediators of inflammation, eosinophils probably contribute to chronic inflammation, including the development of fibrosis. Eosinophils are a major source of the fibrosis-promoting cytokine TGF- β in nodular sclerosing Hodgkin's disease and idiopathic pulmonary fibrosis. Additional roles of eosinophils in modulating extracellular matrix deposition and remodeling are suggested by studies of normal wound healing. During dermal wound healing eosinophils infiltrate into the wound sites and sequentially express TGF- α early and TGF- β ₁ later during wound healing. Of note, whereas experimental administration of neutralizing anti-IL-5 monoclonal antibodies to subjects with asthma had no apparent benefit on some clinical measures of asthma,¹⁷ anti-IL-5 monoclonal antibody has been shown to decrease TGF- β and some extracellular matrix components in the airways of asthmatics.¹⁸ These findings suggest that eosinophils may contribute to the more chronic subepithelial airway fibrosis characteristic of chronic asthma.

Additional functions for eosinophils are suggested by the findings that they may be induced to express class II MHC proteins and can function as antigen-presenting cells. Blood eosinophils lack HLA-DR expression, but eosinophils recovered from the airways 48 hours after segmental antigen challenge have been shown to express HLA-DR. Cytokines, including GM-CSF, IL-3, IL-4 and IFN- γ , induce eosinophil HLA-DR

expression. Both murine and human eosinophils can function as HLA-DR-dependent MHC-restricted antigen-presenting cells in stimulating proliferation of T cells. *In vivo*, murine eosinophils can process exogenous antigens in the airways, traffic to regional lymph nodes, and function as antigen-specific antigen-presenting cells to stimulate responses of CD4 T cells.¹⁹

Because eosinophils normally become resident in submucosal tissues, they undoubtedly participate in ongoing homeostatic immune responses at these sites. Eosinophils are even found in the thymus. Further investigations will help delineate their functional roles and interactions with other cells, including lymphocytes, so that the scope of eosinophil function will probably extend beyond its currently more defined role as an effector cell contributing to allergic inflammation.

■ EOSINOPHILIA AND EOSINOPHILIC DISORDERS ■

Diverse infectious, allergic, neoplastic and idiopathic disease processes can be associated with increased blood and/or tissue eosinophil numbers. Blood eosinophilia, present when eosinophil numbers are in excess of their usual level of less than 450/ μ L of blood, may be intermittently, modestly or less frequently markedly increased. Blood eosinophil numbers are not necessarily indicative of the extent of eosinophil involvement in affected tissues.

Some patients with sustained blood eosinophilia can develop organ damage, especially cardiac. This cardiac involvement can include the formation of intraventricular thrombi and endomyocardial fibrosis with secondary mitral or tricuspid regurgitation (Fig. 23.3). Such damage can complicate the sustained eosinophilia of hypereosinophilic syndromes and has been noted with eosinophilias accompanying other diseases, including eosinophilia with carcinomas or Hodgkin's or non-Hodgkin's lymphomas, and eosinophilia from GM-CSF or IL-2 administration, drug-reactions, and parasitic infections. Most patients with eosinophilia, however, develop no evidence of endomyocardial damage. Conversely, cardiac disease can rarely present in patients without known eosinophilia. The pathogenesis of eosinophil-mediated cardiac damage involves both usually heightened numbers of eosinophils and some activating events, as yet ill-defined, that promote eosinophil-mediated tissue damage.

Cardiac damage progresses through three stages. In the first, there is damage to the endocardium and infiltration of the myocardium with eosinophils and lymphocytes, with eosinophil degranulation and myocardial necrosis. A similar acute eosinophilic myocarditis can develop with drug hypersensitivity reactions and may be more fulminant. The first stage is frequently clinically occult, although splinter hemorrhages may be prominent. Elevations of serum troponins as a measure of myocardial injury should be evaluated. Echocardiography usually detects no abnormalities at this stage. Uncommonly, death due to acute progressive cardiac disease can occur. Corticosteroid therapy during the acute stage may help control and prevent the evolution of myocardial fibrosis.

The second stage of heart disease, the formation of thrombi along the damaged endocardium, affects either or both ventricles and occasionally the atrium. Outflow tracts near the aortic and pulmonic valves are usually spared. These thrombi can embolize to the brain and elsewhere. Finally, in the fibrotic stage, progressive scarring leads to entrapment of chordae tendineae with the development of mitral and/or tricuspid valve regurgitation and to endomyocardial fibrosis, producing a restrictive

Fig. 23.3 Eosinophil endomyocardial disease. A large thrombus is present in the apex of the left ventricle and the chordae tendineae are entrapped, leading to severe mitral valve regurgitation.

cardiomyopathy. Echocardiography and magnetic resonance imaging (MRI) are valuable in detecting intracardiac thrombi and the manifestations of fibrosis. Patients with sustained eosinophilia should be monitored by echocardiography and serum troponin assays for evidence of cardiac disease. In an older series of patients referred to the NIH, much of the mortality in these patients with hypereosinophilia was attributable to end-stage congestive heart failure. In contemporary times, mitral valve replacement with bioprostheses²⁰ and additional therapeutic options for hypereosinophilic syndromes (see below) have largely minimized the morbidity and mortality attributable to end-stage eosinophilic endomyocardial disease.

■ INFECTIOUS DISEASES ASSOCIATED WITH EOSINOPHILIA ■

Eosinophilia is encountered only with specific infectious diseases. With active bacterial or viral infections, eosinopenia is characteristic. This suppression of blood eosinophils is due in part to heightened endogenous corticosteroid production as well as to inflammatory mediators released during these infections. This suppression of eosinophilia, with either serious bacterial infections or marked inflammation, accounts for the absence of otherwise expected eosinophilia in some patients with helminth infections, including those with hyperinfection strongyloidiasis.²¹ As a general clinical guideline, patients with a febrile illness and an increased or even normal blood eosinophilia are not likely to have common bacterial or viral infections, unless they have adrenal insufficiency or a confounding medication-elicited eosinophilia.

HELMINTH PARASITES

Helminth parasites are multicellular metazoan organisms – the ‘worm’ parasites. Infections with diverse helminths elicit eosinophilia.²¹ Although eosinophilia may provide a hematologic clue to the presence

Table 23.1 Parasitic diseases capable of causing marked (>3000/ μ L) or long-standing eosinophilia (Adapted from Wilson ME, Weller PF. Eosinophilia. In: Guerrant RL, Walker DH, Weller PF, eds. Tropical infectious diseases: principles, pathogens and practice, 2nd edn. Philadelphia: Churchill Livingstone, 2006; 1482)

Helminth infection	Hypereosinophilia	Chronic eosinophilia
<i>Angiostrongylus costaricensis</i>	+	
Ascariasis	+ during early lung migration	
Hookworm infection	+ during early lung migration	+ common cause of low-grade eosinophilia
Strongyloidiasis	+	+ self-perpetuating, may last >50 years
Trichinosis	+ with heavy infections	
Visceral larva migrans	+ principally in children	
Gnathostomiasis	+	+
Cysticercosis		+
Echinococcosis		+ may be episodic with cyst fluid leakage
Filariases:		
Tropical pulmonary eosinophilia	+	+
Loiasis	+ especially in expatriates	+
Onchocerciasis	+	+
Flukes:		
Schistosomiasis	+ during early infection in nonimmunes	+
Fascioliasis	+ during early infection	+
Clonorchiasis	+ during early infection	+
Paragonimiasis	+ during early infection	+
Fasciolopsiasis	+ during early infection	+

of helminth infection, the absence of blood eosinophilia does not exclude such infections. The eosinophilic response to helminths is determined both by the host's immune response and by the parasite, including its distribution, migration and development within the infected host. The level of eosinophilia tends to parallel the magnitude and extent of tissue invasion by helminth larvae or adults. For several helminth infections the migration of infecting larvae or subsequent developmental stages through tissues is greatest early in infection, and hence the magnitude of the elicited eosinophilia will be the greatest in these early phases. For established infections, local eosinophil infiltration will often be present around helminths within tissues, without a significant blood eosinophilia. Eosinophilia may be absent in those helminth infections that are well contained within tissues (e.g., intact echinococcal cysts) or are solely intraluminal within the intestinal tract (e.g., *Ascaris*, tapeworms). For some established infections, increases in blood eosinophilia may be episodic. Intermittent leakage of cyst fluids from echinococcal cysts can transiently stimulate increases in blood eosinophilia and also cause symptoms attributable to allergic or anaphylactic reactions (urticaria, bronchospasm). For tissue-dwelling helminths, increases in eosinophilia may occur principally in association with migration of adult parasites, as in loiasis and gnathostomiasis.

Helminth infections more likely to elicit prolonged hypereosinophilia in adults include filarial and hookworm infections and strongyloidiasis (Table 23.1).²¹ Trichinellosis can elicit an acute hypereosinophilia. *Strongyloides stercoralis*, difficult to diagnose solely by stool examinations, is especially important to exclude, not only because it elicits modest to even marked eosinophilia, but also because, unlike other helminths, it

can develop into a disseminated, often fatal, disease (hyperinfection syndrome) in patients given immunosuppressive corticosteroids.²¹ An ELISA serology has proved valuable in detecting strongyloidiasis and should be considered for eosinophilic patients likely to receive corticosteroids. Some tissue- or blood-dwelling helminths that are not diagnosable by stool examinations but which can cause marked eosinophilia require diagnostic examination of blood or biopsied tissues or specific serologic tests.²¹ Infections with these include filarial infections, trichinellosis and visceral larva migrans. In children, owing to their propensity for geophagous pica and ingestion of dirt contaminated by dog ascarid eggs, visceral larva migrans due to *Toxocara canis* is a potential etiology for sustained eosinophilia. ELISA serologic testing can evaluate this possibility.

OTHER INFECTIONS: PROTOZOA AND FUNGI

Infections with single-celled protozoan parasites do not characteristically elicit eosinophilia. This is true of all intestinal, blood- and tissue-infecting protozoa, with two exceptions. Two intestinal protozoans, *Dientamoeba fragilis* and *Isospora belli*, can at times be associated with low-grade eosinophilia. Hence, in patients with symptoms of enteric infection and eosinophilia, diagnostic trophozoites of *D. fragilis* or oocysts of *I. belli* should be sought in stool examinations. Fecal examinations for *I. belli* oocysts must be specifically requested, as they are not usually detected in routine stool ova and parasite examinations. Other enteric protozoa do not elicit eosinophilia and, if detected in stool examinations, should not be accepted as causes of eosinophilia.

Two fungal diseases may be associated with eosinophilia. Aspergillosis is accompanied by eosinophilia only in the form of allergic bronchopulmonary aspergillosis, not when it is an invasive pathogen. Coccidioidomycosis, following primary infection, especially in conjunction with erythema nodosum, and at times with progressive disseminated disease, may elicit blood eosinophilia and may cause an eosinophilic meningitis.²¹

HIV AND RETROVIRAL INFECTIONS

Eosinophilia may uncommonly accompany HIV infections for several reasons. First, leukopenia may increase eosinophil percentages without reflecting true eosinophilia. Second, adverse reactions to medications may elicit eosinophilia. Third, patients with AIDS who develop adrenal insufficiency due to cytomegalovirus and other infections may exhibit eosinophilia as a consequence. In addition, usually modest, and uncommonly marked eosinophilia, is observed in some HIV-infected patients.²¹ Eosinophilia also develops with HTLV-1 infections.²¹

ALLERGIC DISEASES ASSOCIATED WITH EOSINOPHILIA

Among the noninfectious diseases associated with eosinophilia (Table 23.2) are allergic diseases, notably those mediated by IgE-dependent mechanisms. In these diseases, including allergic rhinitis, conjunctivitis and asthma, eosinophils are present in involved tissues as well as often being increased in the blood.

MYELOPROLIFERATIVE AND NEOPLASTIC DISEASE

Eosinophilia may occur with specific neoplastic diseases, as well as in some disorders of uncertain etiology, including some hypereosinophilic syndromes.

HYPEREOSINOPHILIC SYNDROMES

A syndrome previously termed the idiopathic hypereosinophilic syndrome (HES) is not a single entity but rather a constellation of leukoproliferative disorders characterized by sustained overproduction of eosinophils. The three original diagnostic criteria for this syndrome are: eosinophilia in excess of 1500/ μ L of blood persisting for longer than 6 months; lack of an identifiable parasitic, allergic or other etiology for

eosinophilia and an absence of other eosinophilic syndromes clinically distinct from the hypereosinophilic syndrome; and signs and symptoms of organ involvement. In contemporary practice, one can no longer wait for 6 months before diagnostic and therapeutic interventions are needed for a hypereosinophilic patient with organ involvement. Moreover, in recent years there has been increasing recognition that hypereosinophilic syndromes (HESs) encompass a spectrum of disorders, and notable progress has been made in identifying the underlying defects in some of these (Fig. 23.4).²²⁻²⁵

It has been known that some patients with HESs exhibit features common to myeloproliferative disorders, including elevated vitamin B₁₂ levels, splenomegaly, cytogenetic abnormalities, myelofibrosis, anemia, and myeloid dysplasia. In some of these with myeloproliferative HESs, the molecular defect has been identified as a chromosome 4 deletion that yields a fusion gene encoding a FIP1LI/PDGFR α (platelet-derived growth factor- α receptor) (F/P) protein that constitutively expresses receptor kinase activity.²⁶ This fusion gene can be diagnostically evaluated by RT-PCR or FISH (fluorescence *in situ* hybridization) (Chapter 101). Importantly, many of these patients respond to therapy with imatinib.^{26, 27} Other eosinophilic patients without F/P mutations have also responded to imatinib, suggesting that other receptor tyrosine kinase mutations may underlie some of these myeloproliferative forms of HES. In addition, clonal abnormalities in the eosinophil lineage have been reported in few patients, and others may exhibit myeloproliferative features without detected F/P mutations (Fig. 23.4).

Another variant form of HES is a lymphoproliferative form due to clonal expansions of lymphocytes, often CD4⁺CD3⁺ Th2-like, that elaborate IL-5.²³ These aberrant T cells can be sought by flow cytometry or T-cell receptor analysis. These patients, who may have elevated IgE levels, usually do not develop eosinophilic cardiac disease, but are at risk for developing T-cell lymphomas.²³

In addition to these recognized variants, there are yet a substantial number of HES patients for whom the etiology of the eosinophilia remains unknown. Some such patients develop no signs or symptoms of disease and can be followed without therapy. For those who require therapy, including those with lymphoproliferative variants, glucocorticosteroids are the mainstay of treatment.²² Second-line agents include hydroxyurea and IFN- α ,^{22, 28} although IFN- α is not advised for monotherapy of lymphoproliferative variants.²³ A neutralizing anti-IL-5 monoclonal antibody (mepolizumab) is being studied as a potential therapy of F/P-negative HES patients.

EOSINOPHILIA WITH TUMORS OR LEUKEMIAS

The F/P-positive myeloproliferative variant of HES can be considered a form of chronic eosinophilic leukemia.²⁶ Eosinophilia is a characteristic of the M4Eo subtype of acute myeloid leukemia, having the common M4 characteristic of chromosomal 16 abnormalities. Other forms of eosinophilic leukemia, often with specific cytogenetic and molecular genetic abnormalities, have been recognized.²⁹ Eosinophilia may accompany chronic myelogenous leukemia (often with basophilia), but is uncommon with acute lymphoblastic leukemia. Eosinophilia may accompany some lymphomas, including Hodgkin's disease, especially the nodular sclerosing form, T-cell lymphoblastic lymphoma, and adult T-cell leukemia/lymphoma. A small proportion of patients with carcinomas, especially of mucin-producing epithelial cell origin, have associated blood and tissue eosinophilia. Eosinophilia may accompany

KEY CONCEPTS

HYPEREOSINOPHILIC SYNDROMES

- >> Eosinophilia sustained in excess of 1500/ μ L.
- >> Absence of allergic, parasitic, or other etiologies for eosinophilia and distinction from other eosinophilic, organ-limited diseases.
- >> Evidence of organ involvement.

Table 23.2 Eosinophil-associated diseases and disorders (Adapted from Weller PF. Eosinophilia and eosinophil-related disorders. In: Adkinson NF Jr, Yunginger JW, Busse WW, et al., eds. *Allergy: principles and practice*, 6th edn. Philadelphia: Mosby, 2003; 1105)

Allergic or atopic diseases

Myeloproliferative and neoplastic disorders

Hypereosinophilic syndromes: myeloproliferative, lymphoproliferative and others

Leukemia

Lymphoma- and tumor-associated

Mastocytosis

Pulmonary syndromes

Parasite-induced eosinophilic lung diseases:

Loeffler syndrome: patchy migratory infiltrates, resolving over weeks, seen with transpulmonary migration of helminth parasites, especially *Ascaris*

Tropical pulmonary eosinophilia: miliary lesions and fibrosis; heightened immune response causing one form of lymphatic filariasis; increased IgE and antifilarial antibodies

Pulmonary parenchymal invasion: paragonimiasis

Heavy hematogenous seeding with helminths: trichinellosis, schistosomiasis, larva migrans

Allergic bronchopulmonary aspergillosis

Chronic eosinophilic pneumonia: dense peripheral infiltrates, fever; progressive, blood eosinophilia may be absent; steroid responsive

Acute eosinophilic pneumonia: acute presentation diagnosed by bronchoalveolar lavage or biopsy

Churg–Strauss vasculitis: small and medium sized arteries; granulomas, necrosis; asthma often antecedent; extrapulmonary (e.g., neurologic, cutaneous, cardiac, or gastrointestinal) involvement likely

Drug- and toxin-induced eosinophilic lung diseases

Other: hypereosinophilic syndromes, neoplasia, bronchocentric granulomatosis

Skin and subcutaneous diseases

Skin diseases: atopic dermatitis, blistering diseases, including bullous pemphigoid, urticarias, drug reactions

Diseases of pregnancy: pruritic urticarial papules and plaques syndrome, herpes gestationis

Eosinophilic pustular folliculitis

Eosinophilic cellulitis (Wells syndrome)

Kimura's disease and angiolymphoid hyperplasia with eosinophilia

Shulman syndrome (eosinophilic fasciitis)

Episodic angioedema with eosinophilia: recurrent periodic episodes with fever, angioedema, and secondary weight gain; may be long-standing without untoward cardiac dysfunction

Gastrointestinal disorders

Eosinophilic gastroenteritis

Inflammatory bowel disease: eosinophils in lesions; occasionally blood eosinophilia with ulcerative colitis

Rheumatologic diseases

Vasculitis: Churg–Strauss and cutaneous necrotizing eosinophilic vasculitis

Immunologic reactions

Medication-related eosinophilias

Immunodeficiency diseases: Job syndrome and Omenn's syndrome

Transplant rejections

Endocrine

Hypoadrenalism: Addison's disease, adrenal hemorrhage, hypopituitarism

Other causes of eosinophilia

Atheromatous cholesterol embolization

Hereditary

Serosal surface irritation, including peritoneal dialysis and pleural eosinophilia

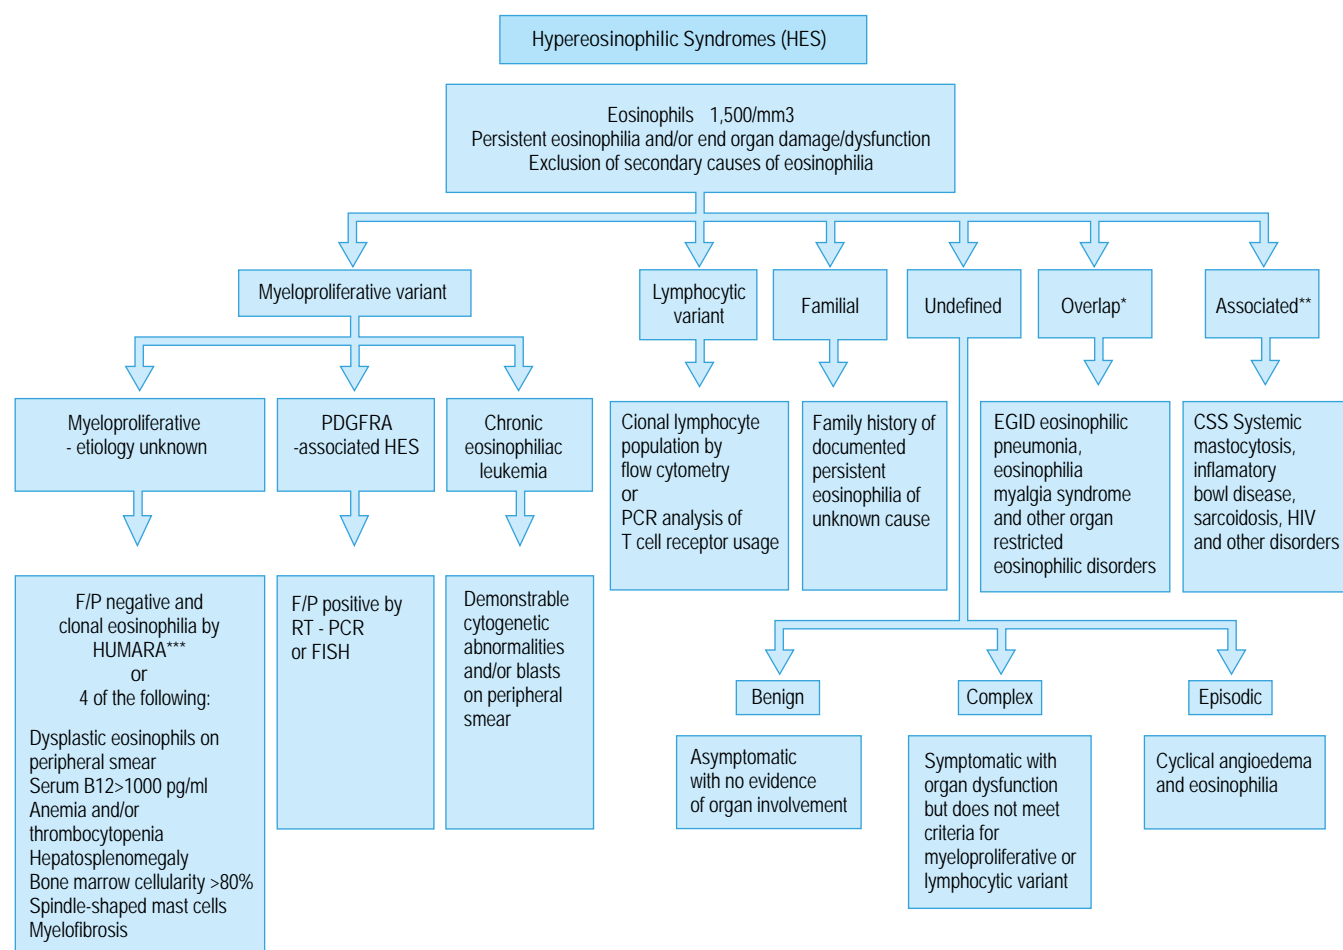

Fig. 23.4 Classification of hypereosinophilic syndromes based on a Workshop Summary report. Specific syndromes discussed at the workshop are indicated in bold. *Incomplete criteria, apparent restriction to specific tissues/organs. **Peripheral eosinophilia, 1500/mm³ in association with a defined diagnosis. †Presence of the *FLPL1/PDGFRA* mutation. *** Clonality analysis based on the digestion of genomic DNA with methylation-sensitive restriction enzymes followed by PCR amplification of the CAG repeat at the human androgen receptor gene (HUMARA) locus at the X chromosome. FISH, fluorescence *in situ* hybridization. (From Klion AD et al. Approaches to the treatment of hypereosinophilic syndromes: A workshop summary report. *J Allergy Clin Immunol* 2006; 117: 1294, with permission from the American Academy of Allergy, Asthma and Immunology.)

angioimmunoblastic lymphadenopathy, mycosis fungoides, Sézary syndrome and lymphomatoid papulosis. Eosinophilia occurs in about 20% of those with systemic mastocytosis and may be the presenting finding in the absence of cutaneous manifestations.

ORGAN SYSTEM INVOLVEMENT AND EOSINOPHILIA

Eosinophilic syndromes limited to specific organs, such as eosinophilic pneumonias³⁰ or eosinophilic gastroenteritides (Chapter 46), characteristically do not extend beyond their own target organ, and hence lack the multiplicity of organ involvement often found with nonorgan-specific hypereosinophilic syndromes. They also do not have the predilection to develop secondary eosinophil-mediated cardiac damage, for reasons that are not known.

PULMONARY EOSINOPHILIAS

Blood eosinophilia can infrequently accompany pleural fluid eosinophilia, which is a nonspecific response seen with various disorders, including trauma and repeated thoracenteses. In addition, several pulmonary parenchymal disorders may be associated with eosinophilia (Table 23.2).

Helminth parasites are responsible for four forms of eosinophilic lung disease.²¹ The first of these is Loeffler's syndrome, which is marked by blood eosinophilia, eosinophilic patchy pulmonary infiltrates that appear and resolve over weeks and, at times, bronchospasm. This syndrome is typically caused by those helminth parasites (*Ascaris lumbricoides*, and less commonly hookworm and *Strongyloides*) that migrate through the lungs early in their developmental lifecycle.²¹ Stool examinations are not helpful, as the pulmonary response is elicited by infecting larval forms months before productive egg-laying

from later adult stages begins in the intestines. Diagnosis is made on epidemiologic grounds.²¹

The second form of helminth-induced lung disease is the syndrome of tropical pulmonary eosinophilia, which develops in a minority of patients infected with lymphatic-dwelling filarial species.²¹ This syndrome is characterized by marked blood eosinophilia, a paroxysmal nonproductive cough, wheezing, and occasional weight loss, lymphadenopathy and low-grade fevers. On chest X-rays increased bronchovesicular markings, diffuse interstitial lesions 1–3 mm in diameter or mottled opacities, usually more prominent in lower lung fields, are common. Patients have markedly increased numbers of blood and alveolar eosinophils, and elevations in both total serum IgE and anti-filarial antibodies.

A third form of helminth-induced lung disease is caused by helminths that invade the pulmonary parenchyma, notably lung flukes that cause paragonimiasis. The fourth form of lung disease is caused by larger than usual numbers of helminth organisms that are carried hematogenously into the lungs. Examples include schistosomiasis, trichinellosis and larva migrans.

Bronchopulmonary aspergillosis constitutes another type of eosinophil-associated pulmonary disease. Two forms of idiopathic eosinophilic pneumonia are recognized. In chronic eosinophilic pneumonia patients may exhibit peripheral pulmonary infiltrates that may extend across lobar fissures.³⁰ Uncommonly, chronic eosinophilic pneumonia is antecedent to Churg–Strauss syndrome vasculitis.³⁰ Blood eosinophilia is present in most patients, but not all. This disease of unknown etiology is responsive to corticosteroids, but prone to relapse.³⁰ An acute form of eosinophilic pneumonia, manifest by fever, pulmonary infiltrates and respiratory insufficiency, is diagnosable by finding eosinophils in bronchoalveolar lavage fluids or on lung biopsy.³⁰ Acute eosinophilic pneumonia, which often follows new exposures to smoke or dusts, responds to corticosteroid treatment and does not relapse.^{30, 31}

The major vasculitis associated with eosinophilia is the Churg–Strauss syndrome (Chapter 58). Late-onset asthma, eosinophilia, and at times transient pulmonary infiltrates, antedate the development of systemic vasculitis in about half of cases. Pulmonary involvement is seen in almost all patients, and pulmonary infiltrates occur in three-quarters. Nasal and sinus involvement is common. Corticosteroids or anti-cysteinyl leukotriene agent therapies for asthma may mask the evolution of Churg–Strauss syndrome. Neurologic, cutaneous, cardiac and gastrointestinal organ involvement is common (Chapter 58).³² Cardiac involvement includes pericarditis and small vessel cardiac vasculitis, and much less commonly endomyocardial thrombosis and fibrosis.

Diverse medications and other drugs are capable of eliciting pulmonary eosinophilia.³³ More commonly implicated medications include nonsteroidal anti-inflammatory drugs (NSAIDs) and antimicrobial medications. Likewise, toxic agents, including from occupational exposure, can be responsible for pulmonary eosinophilia. Each of these reactions has a defined etiologic stimulus and hence differs from idiopathic and other eosinophilic diseases, but the clinical presentation of drug- and toxin-elicited pulmonary eosinophilias can resemble other forms of pulmonary eosinophilia, including acute or chronic eosinophilic pneumonia.

SKIN AND SUBCUTANEOUS DISEASES

A number of cutaneous diseases can be associated with heightened blood eosinophils, including atopic dermatitis, blistering disorders including bullous pemphigoid, drug reactions, and two diseases associated with

pregnancy, herpes gestationis and the syndrome of pruritic urticarial papules and plaques of pregnancy. Eosinophilic pustular folliculitis is seen mostly in patients with HIV infections and in those treated for hematologic malignancies or after bone marrow transplantation. For patients with cutaneous involvement and eosinophilia, angiolymphoid hyperplasia with eosinophilia and Kimura's disease, eosinophilic cellulitis (Wells syndrome), eosinophilic fasciitis, and eosinophilic pustular folliculitis can be differentiated based on the histopathology of biopsied lesions. Another syndrome, episodic angioedema with eosinophilia, is characterized by recurring episodes of angioedema, urticaria, fever, and marked blood eosinophilia. The clinical course of this disease, with its prominent periodic occurrences of angioedema and eosinophilia and its lack of association with cardiac damage, distinguishes it among hypereosinophilic syndromes. This syndrome of unknown etiology responds to glucocorticosteroid therapy.

GASTROINTESTINAL DISEASES

Eosinophilic gastroenteritis represents a heterogeneous collection of disorders in which there may be eosinophilic infiltration of the mucosa, the muscle layer or the serosa, the last of which can lead to eosinophilic ascites (Chapter 24).³⁴ Eosinophils are present in the lesions of collagenous colitis and ulcerative colitis, but blood eosinophilia is usually absent. Gastrointestinal eosinophilia elicited by intestinal helminths and eosinophilic enterocolitis due to hypersensitivity reactions to medications must be excluded in patients with these diseases who have tissue eosinophilia.

RHEUMATOLOGIC DISORDERS

Of the various forms of vasculitis, only two are commonly associated with eosinophilia. The principal eosinophil-related vasculitis is the Churg–Strauss syndrome (as discussed above; Chapter 58). Cutaneous necrotizing eosinophilic vasculitis with hypocomplementemia and eosinophilia is a distinct vasculitis of small dermal vessels that are extensively infiltrated with eosinophils. This form of vasculitis may occur in patients with connective tissue diseases. In addition, eosinophilia may uncommonly accompany rheumatoid arthritis itself, but is more commonly due to adverse reactions to treatment medications (including NSAIDs, gold and tetracyclines) or due to concomitant vasculitis. An uncommon disorder, characterized by the association of nodules, eosinophilia, rheumatism, dermatitis and swelling (NERDS), includes prominent para-articular nodules, recurrent urticaria with angioedema, and tissue and blood eosinophilia.

IMMUNOLOGIC DISORDERS

Adverse reactions to medications are a common cause of eosinophilia (Chapter 48). Although often considered as hypersensitivity reactions, in most instances of drug-associated eosinophilia the mechanism leading to eosinophilia is not understood. Eosinophilia may develop without other manifestations of adverse drug reactions, such as rashes or drug fevers. In addition, drug-induced eosinophilia may be associated with distinct clinicopathologic patterns in which eosinophilia accompanies drug-induced diseases that are characteristically limited to specific organs with or without associated blood eosinophilia. When organ dysfunction develops, cessation of drug administration is necessary. Drug-induced interstitial nephritis may be accompanied by blood eosinophilia, and eosinophils may be detectable in urine.³⁵ Unlike G-CSF therapy, therapy with GM-CSF

CLINICAL PEARLS

EOSINOPHILIA AND DRUG REACTIONS

Drug reactions

Interstitial nephritis
 Pulmonary infiltrates
 Pleuropulmonary
 Hepatitis
 Hypersensitivity vasculitis
 Asthma, nasal polyps
 Eosinophilia-myalgia
 Asymptomatic
 Cytokine-mediated
 DRESS (drug reaction with eosinophilia and systemic symptoms)

Examples

Semisynthetic penicillins, cephalosporins
 Nitrofurantoin, sulfas, NSAIDs
 Dantrolene
 Semisynthetic penicillins, tetracyclines
 Allopurinol, phenytoin
 Aspirin
 L-Tryptophan contaminant syndrome
 Ampicillin, penicillins, cephalosporins
 GM-CSF, IL-2
 Minocycline, allopurinol, anticonvulsants

Adapted from Weller PF. Eosinophilia and eosinophil-related disorders. In: Adkinson NF Jr, Yunginger JW, Busse WW, et al., eds. Allergy: principles and practice, 6th edn. Philadelphia: Mosby, 2003; 1105.

can lead to prominent blood and tissue eosinophilia. Administration of IL-2 or of IL-2-stimulated lymphocytes is also frequently followed by the development of eosinophilia, most likely due to stimulated production of IL-5. Reactions to medications, often anticonvulsants, minocycline and Allopurinol, can elicit DRESS, *drug reaction with eosinophilia and systemic symptoms*.³⁶ In addition to cutaneous eruptions, fever, lymphadenopathy, hepatitis, nephritis, eosinophilia are common but variable elements of this drug-induced syndrome, which can be fatal. The triggering medication must be stopped, and corticosteroids are often administered.

Some primary immunodeficiency syndromes are associated with eosinophilia. The hyper-IgE syndrome is characterized by recurrent staphylococcal abscesses of the skin, lungs and other sites, pruritic dermatitis, hyperimmunoglobulinemia E, and eosinophilia of the blood, sputum and tissues. Eosinophilia is characteristic of Omenn's syndrome, combined immunodeficiency with hypereosinophilia (Chapter 35).

Infiltration of eosinophils accompanies rejection of lung, kidney, and liver allografts. Tissue and blood eosinophilia occur early in the rejection process, and eosinophil counts and granule protein levels (in urine, bronchoalveolar lavage fluids and in involved allograft tissues) have correlated with prognosis, severity, and response to rejection therapy.

ENDOCRINE DISEASES

The loss of endogenous adrenoglucocorticosteroid production in Addison's disease, adrenal hemorrhage or hypopituitarism can cause increased blood eosinophilia.

OTHER CAUSES OF EOSINOPHILIA

The syndrome of atheromatous cholesterol embolization is at times associated with hypocomplementemia, eosinophilia and eosinophiluria. Uncommonly, kindreds with hereditary eosinophilia have been recognized. Irritation of serosal surfaces can be associated with eosinophilia, and related diseases can include Dressler's syndrome; eosinophilic pleural effusions; peritoneal, and at times blood, eosinophilia developing during chronic peritoneal dialysis; and perhaps the eosinophilia that follows abdominal irradiation.

EVALUATION OF EOSINOPHILIA

Because a diversity of disorders may be accompanied by eosinophilia, evaluation of the patient with eosinophilia requires a consideration of features based on the patient's history, physical examination, and other laboratory, radiographic or diagnostic testing.³⁷ An initial approach can focus on identifying eosinophilic diseases that have a defined treatable etiology. These include infections with helminth parasites, and for these the approach should be guided by information obtained from the history regarding potential exposures;³⁸ from the history and physical examinations regarding signs and symptoms of any clinically apparent associated illness; from standard biochemical and radiographic testing for evidence of organ involvement; and from specific parasitologic tests, including potentially stool, urine, blood, sputum or tissue examinations, as well as serologic tests.²¹ The duration and magnitude of the eosinophilia may help suggest some entities, especially if it is prolonged or markedly elevated (see Table 23.1). Other causes of eosinophilia that are amenable to treatment include eosinophilia secondary to medications, for which cessation of the offending drug may be indicated if the eosinophilia is accompanied by organ damage. Likewise, if eosinophilia is secondary to glucocorticosteroid deficiency, diagnostic testing can corroborate this deficiency and lead to the administration of replacement corticosteroids and consequent resolution of the eosinophilia.

Because allergic diseases usually are associated with at least some degree of eosinophilia, clinical and laboratory evidence of such disease should be sought. If the eosinophilia is not attributable to allergic diseases, parasitic infections, medications or steroid deficiency, further evaluation will be guided by whether the patient has evidence of organ disease and which organs are involved (see Table 23.2). This is germane, for instance, in defining whether the patient has a distinct eosinophilic pulmonary, gastrointestinal or cutaneous syndrome. Bone marrow examinations in most patients with eosinophilia are not usually informative, revealing only evidence of enhanced eosinophilopoiesis; but marrow should be examined if there is concern for a hematologic malignancy or myeloproliferative

THERAPEUTIC PRINCIPLES

THERAPY OF SPECIFIC EOSINOPHILIC DISEASES

Eosinophil-associated diseases with identifiable etiologies

Parasitic infections
Drug-reaction related eosinophilias
Adrenal insufficiency
Allergic/atopic diseases

Treat causative parasite
Terminate eliciting medication
Corticosteroid replacement therapy
Varied, may include topical or inhaled corticosteroids

Distinct idiopathic eosinophilic syndromes involving specific organs

Eosinophilic pulmonary diseases
Acute eosinophilic pneumonia
Chronic eosinophilic pneumonia
Churg–Strauss vasculitis

Corticosteroids
Corticosteroids, interferon- α
Corticosteroids, interferon- α

Hypereosinophilic syndromes

F/P-positive myeloproliferative
Lymphoproliferative and other

Imatinib
Corticosteroids, interferon- α , hydroxyurea, anti-IL-5
monoclonal antibody, other

disorder. For patients with sustained eosinophilia who meet the criteria for HES (see Box 23.2), diagnostic testing should aim to identify which variant form of HES the patient may have (see Fig. 23.4).

Immune response to extracellular bacteria

David S. Stephens, William M. Shafer

24

The human host has evolved protective mechanisms to deal with the multitude of bacterial species encountered in nature. These host defenses include nonspecific mechanisms of clearance, and innate as well as specific adaptive immune responses. Partly because of these mechanisms, the vast majority of bacterial species (e.g., ~10 000 different species of bacteria per gram of soil) do not cause human disease. A smaller number of bacterial species (~10³) have established symbiotic or commensal relationships with the human host and colonize skin and mucosal surfaces.¹ These commensals are generally of low virulence except in individuals whose host defenses are compromised. A few (~10²) pathogenic bacterial species or subpopulations of those species have evolved virulence factors or strategies that can overcome or circumvent human host defense mechanisms and cause local or invasive clinical disease. In fact, defects in host defenses are often suggested by the infecting bacteria (Table 24.1). Many of these bacterial pathogens reside mostly extracellularly. Examples are pathogens such as *Neisseria meningitidis*, *Neisseria gonorrhoeae*, *Haemophilus influenzae*, group A streptococci, *Bordetella pertussis*, and *Streptococcus pneumoniae*, which are transmitted from one individual to another by close contact. Other 'extracellular' bacterial pathogens, such as *Vibrio cholerae*, *Shigella dysenteriae*, enteropathogenic *Escherichia coli*, *Bacillus anthracis* and *Clostridium tetani*, are acquired through food, water, animal or other environmental contact. *Staphylococcus aureus* is an important extracellular pathogen for humans and can be acquired from other humans, animals, or through environmental contacts.

'Extracellular' bacterial pathogens usually produce acute inflammatory and purulent infectious diseases such as meningitis, septicemia, pneumonia, urethritis, pharyngitis, inflammatory diarrhea, cellulitis and abscesses, and/or produce disease by the release of toxins. Disease associated with some extracellular bacteria (e.g., *Helicobacter pylori*) results from chronic colonization. Susceptibility to extracellular bacterial pathogens is enhanced by hereditary, acquired or age-related defects in epithelial, humoral and phagocytic host defenses. Enhanced resistance to extracellular bacterial pathogens or their toxins can be accentuated by chemoprophylaxis, by vaccines, and by other immune modulation processes (passive immune globulin). Caution is urged in the interpretation of the term 'extracellular', as some of these pathogenic bacterial species invade host cells as a part of their normal lifecycle and during steps in the disease process.

■ HOST DEFENSES AND IMMUNE RESPONSES AT EPITHELIAL SURFACES ■

CLEARANCE AND NONSPECIFIC HOST DEFENSES AT EPITHELIAL SURFACES

Intact skin and mucosal surfaces provide a formidable barrier to most bacterial species.² Damage to epithelial barriers by trauma, co-infections, drugs such as those used in chemotherapy, environmental factors such as smoking, allergies or low humidity, catheterization and intubation circumvent these barriers and allow bacteria access to subcutaneous tissues, blood vessels and other normally sterile sites (Table 24.2). Skin is a relatively dry, acidic (pH 5–6) barrier that contains growth-inhibiting fatty acids and antimicrobial peptides (see below),² characteristics that are detrimental to many bacteria. The stratified desquamatory epithelial surface of the skin also helps in the removal of microorganisms. Repeated trauma to skin (e.g., dialysis and IV drug use) enhances skin colonization with pathogens such as *S. aureus*.

Mucosal surfaces have additional nonspecific antibacterial defenses. Lysozyme is found in most mucosal secretions and lyzes bacterial cell walls by splitting muramic acid $\beta(1-4)$ -N-acetyl-glucosamine linkages. The mucociliary blanket of the respiratory tract (Fig. 24.1) and the female urogenital tract (fallopian tube) moves bacteria away from epithelial surfaces, as does the flushing of the urinary tract with urine and the bathing of the conjunctiva with tears. Phospholipase A₂, particularly in tears, has received attention as an antibacterial agent. The acid pH of the stomach, intestinal peristalsis and the antibacterial effect of proteolytic enzymes present in intestinal secretions are important gastrointestinal tract host defenses against bacteria.

The normal flora of the skin, upper respiratory and gastrointestinal tracts, and the genital tract of females, is also a major barrier to colonization by newly acquired pathogens.^{1,3} Altering normal flora or protective barriers, for example by creating pharmacologic or surgical gastric achlorhydria or by the use of broad-spectrum antibiotics, can lead to the acquisition and overgrowth of pathogenic bacteria such as *Salmonella*

Table 24.1 Host defense defects suggested by infecting bacteria

Bacteria	Defective system
Staphylococci, aerobic Gram-negative bacilli	Skin and mucous membrane barriers, phagocyte dysfunction
<i>Haemophilus influenzae</i> , pneumococci	Antibody, mucous membrane barriers
<i>Neisseria meningitidis</i> and <i>Neisseria gonorrhoeae</i>	Complement pathways, antibody
<i>Mycobacterium</i> , <i>Salmonella</i>	Cell-mediated immunity

Immotile cilia syndromes (recurrent sinopulmonary infections with pyogenic bacteria)

Tracheostomy and tracheal intubation (aerobic Gram-negative bacteria)

Urinary tract obstructive lesions and bladder catheters (Gram-negative bacilli)

IV catheters, other mucosal disruption (tumor, ulceration etc.) (*S. aureus* and Gram-negative bacilli, mixed aerobic and anaerobic infections in diabetics)Surgical procedures and skin trauma (*S. aureus*)Burns (aerobic Gram-negative bacilli, *S. aureus*)Smoking (*H. influenzae*, pneumococci, meningococci)Achlorhydria (*Salmonella*, tuberculosis)

Slowing peristalsis with opium alkaloids (prolongs symptomatic shigellosis)

*Alteration of normal flora*Antibiotics: *Candida* overgrowth, *C. difficile* colitisAlcoholism: *Klebsiella* pharyngeal colonization, tuberculosis

Severe illness: colonization of oropharynx by Gram-negative bacilli and nosocomial pneumonias

Alteration of the normal microbial flora by antibiotics, alcoholism and severe illness may lead to colonization or production of disease by extracellular bacteria. For example, colonization of the respiratory tract with aerobic Gram-negative bacilli may follow treatment with broad-spectrum antibiotics that eradicate the normal upper respiratory tract flora. Serious Gram-negative bacilli pneumonia may occur, especially if other host abnormalities are also present

typhimurium, *Clostridium difficile* or antibiotic-resistant Gram-negative bacilli. Normal flora also facilitate a high level of priming of the immune system by maintaining high levels of MHC class II molecule expression on macrophages and other antigen-presenting cells.²

Bacterial attachment and colonization of mucosal surfaces can be inhibited by bacterial binding to human cellular antigens present in secretions, such as ABO blood group antigens. Cell adhesion and extracellular matrix molecules such as fibronectin and proteoglycans can also inhibit or enhance bacterial binding to epithelial surfaces. The Tamm-Horsfall glycoprotein, found in the urine, can bind avidly to a variety of bacteria and facilitate clearance. Proteins such as lactoferrin (LF), present at mucosal surfaces, bind iron, an important requirement for bacterial growth. This action may reduce microbial proliferation, but some mucosal pathogens bind LF and remove iron for growth.

INNATE AND ACQUIRED IMMUNE DEFENSES AT MUCOSAL SURFACES

Immune pattern recognition molecules (Table 24.3) are a major arm of the innate immune system and are released or expressed by a range of host cells, including lymphocytes, macrophages or tissue histiocytes,

dendritic cells, polymorphonuclear leukocytes (PMNs) and epithelial cells (Chapter 3). These cells also protect mucosal surfaces from microbial invasion. In acquired immunity, mucosal immunoglobulins are a major protection against extracellular bacteria.

PATTERN RECOGNITION MOLECULES

The discovery and characterization of specific pattern recognition molecules has revolutionized our understanding of the initial specific events occurring between microbes and human cells. The identification and function of these molecules is rapidly expanding and include Toll-like receptors, NOD and caterpillar proteins, RNA helicases, complement proteins, antimicrobial peptides, collectin and surfactants, C- and S-lectins such as mannose-binding lectin and L-ficolin.⁴⁻⁷ A family of major importance are the Toll-like receptors⁴⁻⁶ (TLR1–10) (Table 24.4) found on macrophages, neutrophils and other host cells. These receptors recognize a variety of microbial ligands or pathogen-associated molecular patterns (PAMPs), including lipoteins, LPS, flagellin and nucleic acids produced by Gram-negative and/or Gram-positive bacteria. Alterations (polymorphisms) in TLRs (e.g., TLR4) and other pattern recognition molecules is associated with susceptibility or severity of specific infections (e.g., sepsis).⁶

DENDRITIC CELLS

Discovered in the early 1970s by Steinman and Cohen,⁸ dendritic cells (DCs) are now recognized as important and potent antigen-processing and -presenting cells that are crucial for the induction of T- and B-cell responses (Chapter 7). They present peptides and proteins to both T and B cells. DCs have been thought of as the pacemaker of the immune response⁹ and are widely distributed in tissues, especially those that interface with the environment. They are a heterogeneous group of antigen-processing cells that arise from three pathways that are lymphoid or myeloid related in their origin. They employ pattern recognition receptors (e.g., TLRs) to detect pathogens (viruses and bacteria) in their environment. In most tissues, DCs are at low levels and are immature, but upon activation

KEY CONCEPTS

HOST DEFENSES AND IMMUNE RESPONSE AT EPITHELIAL SURFACES TO EXTRACELLULAR BACTERIA

- >> Clearance and nonspecific host defenses at skin and mucosal surfaces
 - >> Epithelial barriers
 - >> Antibacterial factors (fatty acids, antibactericidal peptides, lysozyme, phospholipase A₂)
 - >> Mucociliary activity
 - >> Normal flora
 - >> Adherence blocking molecules
- >> Specific immune defenses at mucosal surfaces
 - >> Innate immune mechanism
 - >> Immunoglobulins
 - >> Phagocytosis at mucosal surfaces

 TLR10-lipopeptide PAMPs

they take up and process antigen. DC activation has a number of important consequences in immunity, including activation of naïve T cells. They perform a key role in host defense against viral and bacterial pathogens. Skin contains a major supply of tissue DCs (Langerhans' cells) and their involvement in combating skin and soft tissue infection must be considered along with their function and contribution to stimulating immunity during vaccination. Limited information is available regarding their role in host resistance to extracellular bacteria, but studies have been performed that examine the interaction of bacteria with DCs. For instance, Kolb-Maurer et al.¹⁰ and Unkmeir et al.¹¹ have studied the interaction of serogroup B meningococci with DCs. Infection of DCs by meningococci resulted in a significant and rapid production of proinflammatory cytokines and chemokines, including TNF- α , IL-6 and IL-8 through a lipooligosaccharide (LOS)-dependent mechanism.

LYMPHOCYTES

Mucosa-associated lymphocyte tissue (MALT) is comprised of intraepithelial lymphocytes (IELs), lamina propria lymphocytes and lymphoid follicles (e.g., Peyer's patches), and is sometimes divided into the gut-associated (GALT), bronchial-associated (respiratory tract) (BALT) and genitourinary tract lymphocyte populations¹² (Chapter 19). These cells are important for homeostatic regulation and the maintenance of immune response against microbes at mucosal surfaces, including 'extracellular' bacteria. One in five cells in the intestinal epithelium is a lymphocyte. These cells express pattern recognition receptors (e.g., TLRs), have constitutive cytotoxic activity, secrete chemokines and cytokines important in regulation and host defense, and act in concert with mucosal epithelial cells and exocrine glands. For example, depression of IEL response (e.g., the production of IL-2/IFN- γ), is observed in experimental sepsis and following IEL exposure to lysates of enteropathogenic *E. coli* and other intestinal pathogens. *Helicobacter pylori*-associated gastritis is characterized by cytokine release and increased IEL infiltration, and can result in gastric mucosal lymphoid tissue (MALT) lymphomas. Eradication of *H. pylori* causes a reduction in IEL infiltrates.

MACROPHAGES

Phagocytic cells, macrophages and PMNs are also present at mucosal surfaces (Fig. 24.2). These cells express pattern recognition receptors and migrate to mucosal surfaces by chemotaxis and diapedesis between epithelial cells. Macrophages are also encountered after crossing the epithelial barrier. Specialized epithelial M cells of mucosal surfaces are key sites for antigen sampling, including viruses, and bacteria and macrophages surround these sites.¹³ However, enteroinvasive pathogens such as *Shigella* can resist macrophages. *Shigella* induce macrophage apoptotic death by direct interaction of the bacterial protein IpaB with interleukin-1 β -converting enzyme.¹³ Viral co-infections may prime macrophages for LPS-induced apoptosis.¹⁴

Fig. 24.3 Bacterial resistance to PMNs in the extracellular environment. The two principal mechanisms of bacterial resistance to PMN killing. These consist of resistance to phagocytosis as a result of bacterial surface components (e.g., capsule or pili) and the action of extracellular proteins that can lyse PMNs (e.g., leukocidins) or decrease chemotaxis (e.g., C5a peptidase). Bacteria growing in biofilms may be more protected from PMNs than bacteria growing in the planktonic state.

POLYMORPHONUCLEAR LEUKOCYTES

In areas of epithelial inflammation, polymorphonuclear leukocytes (PMNs) or neutrophils can be recruited to mucosal and skin surfaces. PMNs are more effective in the presence of specific immune defenses, such as antibody and complement components. PMNs express pattern recognition receptors and have both oxygen-dependent and -independent mechanisms of killing (Chapter 21). Extracellular bacteria typically evade these bactericidal processes by resisting phagocytosis (Fig. 24.3). Resistance to phagocytosis can be due to the action of carbohydrate capsules, which impede the engulfment of phagocyte-associated bacteria. Other microbial surface structures, such as the pili of the gonococcus, can 'stiff-arm' neutrophils, keeping them at a distance.¹⁵ A number of pyogenic bacteria (e.g., *S. aureus*) secrete leukocidins, which lyse phagocytes. Other pathogens (e.g., group A streptococci) inhibit chemotaxis of neutrophils through the elaboration of enzymes (e.g., C5a peptidase) that proteolytically cleave chemotactic signals. Regardless of the mechanism by which bacteria resist phagocytes, opsonic antibody can often overcome these forces and promote killing. The importance of PMNs in host defense against extracellular pathogens can best be highlighted by the increased frequency of bacteremias and other life-threatening infections in neutropenic patients or those individuals with neutrophil deficits (e.g., chronic granulomatous disease, Chediak-Higashi syndrome or specific granule deficiency, to name but a few) (Chapter 21).

ANTIMICROBIAL PEPTIDES (AMPs)

Extracellular pathogens are likely to be confronted with both myeloid-derived AMPs (e.g., the α -defensins stored within neutrophil granules) and nonmyeloid antibacterial peptides.¹⁶ These (and similar) peptides,

THERAPEUTIC PRINCIPLES

MANAGING DEFECTS IN HOST DEFENSES

- >> Impaired skin and mucous membrane barriers – protect skin from maceration and injury, frequent change of IV catheters. Antibiotic prophylaxis, such as use of trimethoprim-sulfamethoxazole remains controversial.
- >> Defects or polymorphisms in innate immune mechanisms – may lead to select cytokine use or other adjuvant therapy such as activated protein C in sepsis.
- >> Abnormal humoral immunity – intravenous immune serum globulin.
- >> Complement system abnormalities – fresh plasma or, if available, individual complement components to replace deficient factor.
- >> Defective cell-mediated immunity reversal of malnutrition – reduction in dosage of immunosuppressive drugs (corticosteroids); other therapy in selected patients (transfer factor, bone marrow transplantation, replacement of missing enzymes).
- >> Phagocyte dysfunction – GM-CSF or G-CSF to increase neutrophil numbers.
- >> Immunization with pneumococcal, meningococcal, *H. influenzae* and influenza vaccines in selected patients.

which are typically cationic, amphipathic molecules, represent an integral part of the innate host defense system for humans and other vertebrates, invertebrates and plants.¹⁷ Many of these peptides from evolutionary diverse sources share structural similarities, suggesting their importance in host defense throughout evolution. In general terms, these antimicrobial peptides (often effective at micromolar concentrations *in vitro*) can either be constitutively synthesized (e.g., the α -defensins of neutrophils) or their production can be induced in a variety of epithelial cells (e.g., Paneth cells of the small intestine) by a variety of stimuli, including infection.¹⁸ Humans produce two main classes of AMP: defensins¹⁸ and cathelicidins.¹⁹ Defensins (3–4 kDa) are cysteine-rich peptides and are classified as α - and β -defensins. α -Defensins are major components of neutrophil granules capable of reaching mg/mL concentrations in phagolysosomes and small intestinal Paneth cells. β -Defensins are produced by a large variety of epithelial cells, mucosal surfaces, skin and organs. The circular θ -defensins of rhesus macaques are produced by a unique ligation reaction of two peptides, but owing to a premature stop mutation are not produced by humans; θ -defensins can have potent antiviral effects. Unlike many other vertebrates, humans produce only one cathelicidin (LL-37),¹⁹ which is synthesized by both PMNs and epithelial cells. The 'cathelin' domain of the precursor protein resembles inhibitors of cysteine proteases and is removed by proteolytic cleavage to liberate the LL-37 AMP, an α -helical, linear peptide of 37 amino acids.

AMPs probably exert their lethal effect at the bacterial inner membrane, causing rapid depolarization and loss of membrane potential,²⁰ although some evidence exists that certain peptides have cytosolic targets. Bacteria can avoid these peptides to some extent by reducing the electronegativity of their microbial cell surface, which reduces electrostatic interactions with

cationic regions of the peptide.²¹ The importance of surface binding is further illustrated by the salt-sensitivity of a number of antibacterial peptides. This property has been advanced as one possibility to explain the antimicrobial deficit in lung airway fluid obtained from patients with cystic fibrosis.²² Other mechanisms used by bacteria to subvert the lethal action of AMPs include energy-dependent efflux, proteolytic degradation, modification of membrane phospholipids, production of AMP-binding proteins, reduction of cytoplasmic membrane potential, and biofilm production. The regulation of genes encoding products involved in such resistance has been extensively studied and certain two-component regulatory systems²³ (e.g., *pmrAB* and *phoPQ* in *Salmonella*) or transcriptional regulators can be involved in determining levels of bacterial susceptibility to AMPs.²⁴

AMPs probably contribute to host defense through their antibiotic-like action and by virtue of their immunomodulatory properties. In this respect, they should be viewed more broadly as host defense peptides.²⁵ They can effectively bind and neutralize endotoxin, act as chemokines, and induce chemokine synthesis that results in recruitment and accumulation of phagocytes at sites of infection. AMPs can also promote wound healing, and have been proposed to link innate and adaptive immune responses.^{25, 26} Mice expressing human defensin-5 are more resistant to lethal *Salmonella* infection, providing evidence that human AMPs are important in host defense.²⁷ AMPs present at the human vaginal and cervical mucosal surfaces may also be important in host defense against sexually transmitted infections or in reducing the incidence of vaginosis.²⁸ LL-37 and β -defensins are probably important in the antimicrobial defense of human skin. Mice deficient in the murine version of LL-37 (CRAMP) are more susceptible to group A streptococcal skin and soft tissue infections and invasive disease.²⁴ Patients with psoriasis or atopic dermatitis provide an example of where AMP levels are altered. Thus, keratinocytes of inflamed psoriatic lesions produce increased levels of certain AMPs, and such patients rarely have secondary bacterial infections.²⁶ In contrast, keratinocytes from patients with atopic dermatitis do not overproduce AMPs and often have skin infections caused by *S. aureus*. Human synthesis of β -defensin 2 is significantly decreased in patients with acute burns, which may partly explain their increased susceptibility to *Pseudomonas aeruginosa* infections. The rare patient population with PMN-specific granule deficiency are deficient in defensins and other neutrophil components, and these individuals have life-threatening infections.²⁹ The severe congenital neutrophil deficiency termed morbus Kostmann disease can be treated with G-CSF to restore neutrophil levels, but such phagocytes fail to produce LL-37 and such patients often have frequent and life-threatening infections as well as periodontal disease.³⁰ Thus, taken together, there is increasing evidence that AMPs are important in the overall integrity of the human host defense scheme, and a combination of their antimicrobial and immunomodulatory activities is involved in protection against extracellular pathogens.

IMMUNOGLOBULINS

Immunoglobulins, principally secretory IgA and IgG, are present at mucosal surfaces and in mucosal secretions. Important in the generation of these immunoglobulins at mucosal surfaces is the dissemination of IgA and IgG class-committed B- and T-helper cells with specificity to an antigen encountered and processed at one mucosal site to local and distant mucosal sites. Protective mucosal antibodies against bacteria may be derived from prior colonization, vaccines, or shared cross-reactive antigens on normal flora. Mucosal immunoglobulins may neutralize bacterial toxins, facilitate phagocytosis or bactericidal activity, inhibit

Table 24.5 Bacterial and other infections associated with abnormal humoral immunity

Primary deficiency

Congenital or X-linked agammaglobulinemia (Bruton's agammaglobulinemia) is manifested by recurrent bacterial infections of the middle ear and sinopulmonary tract, often with complicating bacteremias. Infections with enteroviruses also occur

Selective immunoglobulin deficiency: IgA – variable course, often free of infection; IgG, IgG subclass deficiency, IgM – recurrent pyogenic bacterial infections

Common variable immunodeficiency ('acquired' hypogammaglobulinemia) is associated with various bacterial sinopulmonary infections, giardiasis, increased risk of lymphomas and gastric carcinomas

Secondary deficiency

Multiple myeloma and chronic lymphocytic leukemia (CLL) are associated with infections caused by encapsulated bacteria, Gram-negative bacilli, *S. aureus*, and giardiasis

Splenectomy – severe infections with pneumococci, other streptococci, *H. influenzae* and meningococci

bacterial adherence ligands, or sterically hinder other events necessary for bacterial colonization and invasion. Many extracellular bacterial pathogens (*N. meningitidis*, *N. gonorrhoeae*, *H. influenzae*, certain streptococci) colonize and/or infect mucosal surfaces where protective IgA₁ antibodies could become available.³¹ These pathogens secrete an IgA₁ protease that cleaves IgA₁, thereby inactivating it. IgA₁ protease can also recognize other substrates, notably LAMP-1, that are important in host defense. Bacterial infections associated with abnormal immunoglobulin function are summarized in Table 24.5 and Chapter 34.

BACTERIAL PATHOGENS AT EPITHELIAL SURFACES

'Extracellular' bacteria that cause disease in humans are transferred from person to person by direct contact, contact with feces, respiratory droplets or other secretions, or from contaminated food or water. Acquisition of these pathogenic bacteria may be transient, or lead to colonization or local and invasive disease. To colonize human epithelial barriers and mucosal surfaces, bacteria overcome the nonspecific clearance (e.g., mucus, ciliary activity) and other local immune defense mechanisms (e.g., mucosal cellular defenses, immunoglobulins, fatty acids, lactoferrin). For example, bacteria can transverse mucus by expressing motility factors (e.g., pili, flagella), and induce ciliostasis or decrease motility by direct contact or by the release of toxins.

Initial attachment of bacteria to human epithelial cells is, in part, mediated by pili, fimbriae or other bacteria ligands, and close adherence involves the cell wall, outer membrane proteins, lipopolysaccharide and other bacterial surface structures. The attachment of bacteria to human epithelial cells prevents loss from the host. Attachment can also induce cytoskeletal rearrangements, such as elongation and branching of the microvilli, the accumulation of actin, and calcium efflux, which facilitates close adherence and invasion of epithelial cells by normally 'extracellular' bacteria, especially at sites with rapidly moving fluid. The entry of bacteria into epithelial cells

Fig. 24.4 Colonization and adherence of extracellular bacteria at mucosal surfaces. Scanning electron micrograph of *N. meningitidis* adherence and microcolony formation of a human upper respiratory mucosa (×16 250).³⁵

provides access to nutrients and protection from host defenses, allows protected multiplication, and leads to shedding of organisms back to the mucosal surface, to facilitate transmission and further spread of the infection on the epithelium. Attachment can also initiate epithelial cell apoptosis or toxin-mediated cell death and lead to the breakdown of the epithelial barrier.

N. meningitidis (the meningococcus), for example, is transmitted from person to person by large respiratory droplets or close contact with secretions. During the process of colonization of human upper respiratory mucosal surfaces (e.g., the nasopharynx) meningococci utilize phase-variable meningococcal surface ligands and multiple human epithelial cell surface receptors.^{32,33} Meningococci that are acapsulate, piliated, express high levels of the outer membrane protein, Opc (formerly class 5C protein) and the nonsialylated LOS structure containing a terminal Galβ1-4Glu group (L8 immunotype) attach to and interact with human epithelial cells most effectively (Fig. 24.4). These characteristics correspond to the predominant phenotype of meningococci retrieved from the nasopharynx of human carriers. Pili facilitate twitching motility and microcolony formation, which allows the penetration of mucus and provides initial attachment. The outer membrane adhesin, Opc, mediates meningococcal attachment and invasion by binding vitronectin, which attaches to and is internalized by the vitronectin receptor α_vβ₃ found on epithelial cell surfaces.³² Class V (opacity) meningococcal proteins interact directly with members of the carcinoembryonic (CD66) antigen family.³² The expression of a sialic acid capsule and

sialylatable LOS structures, such as the L3,7,9 immunotype, interfere with Opc-mediated attachment and invasion and facilitate spread and transmission.³⁴ Meningococci at mucosal surfaces bind and utilize lactoferrin as an iron source and secrete a protease that cleaves IgA₁. Meningococcal colonization of the human upper respiratory (nasopharyngeal) epithelium is also associated with ciliostasis and sloughing of ciliated cells, which occurs at a distance from the sites of bacterial attachment.^{33, 35} Ciliostasis may be caused by a diffusible toxin, such as LPS, which may directly or indirectly cause cytotoxicity by the induction of inflammatory cytokines. Other cofactors, such as smoking or viral infections, facilitate meningococcal invasion at nasopharyngeal mucosal surfaces.

IMMUNE RESPONSES DURING LOCAL AND SYSTEMIC INVASION BY EXTRACELLULAR BACTERIAL PATHOGENS

Bacteria that breach mucosal and skin barriers and reach submucosal tissues and/or the bloodstream induce immune responses, including cytokine release, phagocytosis, complement activation, antibody release or production, and other local or systemic induction of the inflammatory cascade. The survival of bacteria following colonization of the epithelium and access to the bloodstream depends on the integrity of the host immune response (including variability due to genetic polymorphism) and on the ability of the bacteria to resist this response. Host factors that increase the risk for the development of systemic disease due to extracellular bacteria include polymorphisms in innate immune mechanisms, the absence of bactericidal or opsonizing antibodies, deficiencies in the complement pathways,³⁶ and an absence of or reduction in neutrophil function or levels.

As noted above, immune pattern recognition molecules⁴ expressed or released by a variety of host cells, especially PMNs, monocytes, macrophages and dendritic cells, are important initiators of the immune response to extracellular bacteria. Interaction with microbial ligands (LPS, lipoproteins) leads to chemokine and cytokine release, including TNF- α , IL-1 β , MCP-1, MIP-3a, IL-6, IL-8, 1P-10, MCP-5 and RANTES) mediate the local and systemic inflammatory response to extracellular bacteria.

Phagocytes can ingest bacteria by opsonin-independent (less efficient) or -dependent mechanisms. Mononuclear phagocytes in the blood, liver, spleen and lung remove particles, including bacteria. Complement components, fibronectin or other extracellular matrix proteins that bind to bacteria facilitate recognition. Bacteria ingested by phagocytes are killed by toxic O₂ radicals and/or H₂O₂ through myeloperoxidase-dependent or -independent mechanisms. The elaboration of superoxide dismutase and catalase can reduce the efficacy of O₂-dependent killing of bacteria, but the high levels of O₂ radicals that accumulate in PMNs probably overcomes these bacterial enzymes, as evidenced by the susceptibility of *S. aureus* to intraleukocytic killing. Oxygen-independent systems caused by the action of proteins BPI, CAP 37, cathepsin G, elastase and AMPs (α -defensins and LL-37), also contribute significantly to phagocytic killing. Bacterial infections associated with phagocytic dysfunction are described in Chapters 21 and 31.

Complement, a series of more than 20 proteins, is activated by microbial surfaces (alternative complement cascade) or via antibody or by the mannose-binding lectin system (Chapter 20). Complement activation leads to microbial lysis and the release of opsonins and chemoattractant molecules for phagocytic cells. Complement activity is mediated by the

classic complement pathway, which can be initiated either by antibody binding to cell surface epitopes or by antibody-independent autocatalytic activation of C1 to form C1q. Initiation of the alternative pathways by bacterial products or mannose-binding protein leads to the direct deposition of the C3b complex on the bacterial surface. Complement activation results in the activation of the late components of the complement pathway, which results in the formation of a membrane attack complex (MAC), insertion in the bacterial cell, and bactericidal activity. Gram-positive extracellular pathogens resist the bacteriolytic action of MAC as a result of their thick peptidoglycan layer, which impedes the insertion of MAC C5b-9 complex. Gram-negative bacteria can resist MAC through structural alterations in their LPS (the possession of O antigen keeps MAC at a distance from the bacterial surface) or by masking or deleting the epitope(s) responsible for binding bactericidal antibody. The initiation of the complement cascade is also an essential step in opsonization and the eventual phagocytosis and ingestion of invading bacteria.

In infants, antibacterial activity wanes as levels of passively transferred maternal antibody fall. This waning of antibody is correlated with the highest incidence of several 'extracellular' pyogenic bacterial diseases (*S. pneumoniae*, *N. meningitidis*, *H. influenzae* type b) in young children. During childhood and adolescence, levels of bactericidal antibodies rise and rates of these diseases decline. Specific antibodies are acquired through carriage and through cross-reacting epitopes on other commensal species. For example, cross-reactive antibodies to *N. meningitidis* are acquired by colonization with commensal *Neisseria* spp. (e.g., *Neisseria lactamica*) and unrelated bacteria (e.g., *Enterococcus faecium*, *Bacillus pumilus* and *E. coli*). The lack of bactericidal antibodies against a strain acquired in the upper respiratory tract is an important risk factor for invasive meningococcal disease.

Complement deficiencies, either congenital or acquired, also increase the risk for invasive bacterial diseases (Chapter 20). Because C3 plays a critical role in the complement cascade, congenital C3 deficiency or conditions that reduce C3 (e.g., systemic lupus erythematosus, cirrhosis, nephritis, C3 nephritic factor) increase the risk for invasive disease due to pyogenic bacteria such as *S. pneumoniae* and *N. meningitidis*. Mannose-binding lectin (MBL) is a plasma opsonin that initiates complement activation. MBL gene polymorphisms are found in children with meningococcal and pneumococcal sepsis. Properdin deficiency, leading to defective alternative pathway killing, is also associated with severe and recurrent meningococcal infections. Terminal complement deficiencies (C5–C8) are also associated with recurrent invasive bloodstream meningococcal and gonococcal infections, indicating an important role for insertion of the complement membrane attack complex in the bactericidal activity of human serum against pathogenic *Neisseria*.³⁶ In adults 10–20% of invasive meningococcal disease is associated with a defect in the complement system.³⁶ Enteric colonization by bacteria that have similar antigenic epitopes has been proposed to induce these blocking antibodies. Screening tests useful for the evaluation of humoral, complement and other immune defects are discussed in Chapter 30.

In addition to defects in innate immunity, immunoglobulins and complement deficiencies, human genetic polymorphisms are associated with an increased risk or severity of bacterial diseases. For example, Fc γ IIa (CD32) receptor polymorphisms, Fc γ -receptor III (CD16), MBL, TLR4, TNF promoter region polymorphisms, plasminogen activator and inhibitor expression, and hereditary differences in cytokine induction influence susceptibility to meningococemia.^{37,38} Each of these may influence the course of invasive bacterial infection by influencing the response of the inflammatory cascade.

Table 24.6 Major agents of septicemia

<i>Staphylococcus aureus</i>	
Enterococci	
<i>Streptococcus pneumoniae</i>	
<i>Haemophilus influenzae</i>	
<i>Streptococcus pyogenes</i>	
<i>Streptococcus agalactiae</i>	
Gram-negative aerobic bacilli	
<i>E. coli</i>	<i>Enterobacter</i> spp.
<i>Pseudomonas aeruginosa</i>	<i>Morganella morganii</i>
<i>Serratia marcescens</i>	<i>Proteus mirabilis</i>
<i>Klebsiella pneumoniae</i>	<i>Providencia stuartii</i>
<i>Citrobacter</i> spp.	<i>Acinetobacter</i> spp.
<i>Neisseria meningitidis</i>	<i>Pasteurella</i> spp.

Induction of the inflammatory cascade, acute-phase reaction or response, augments humoral defense components, increases the number and function of phagocytic cells and facilitates the delivery of humoral cellular molecules to sites of bacterial invasion.² Components of this reaction include cytokines, mannose-binding protein, fibronectin, haptoglobin, transferrin, C-reactive protein, platelet-activating factor, prostaglandins, lipopolysaccharide-binding protein (LBP), α_1 -antitrypsin and α_2 -macroglobulin. Acute-phase reaction components induce fever, the catabolism of muscle protein, decrease available iron, increase phagocyte activity, increase vascular permeability, and induce the release of hormones and neurotransmitters.

Pyogenic extracellular bacteria have evolved strategies to avoid or overcome immune responses. For example, meningococci isolated from the bloodstream or cerebrospinal fluid are characteristically encapsulated and express the sialylatable lacto-*N*-neotetraose-containing L3,7,9 LPS immunotype. The co-expression of both of these structures is necessary for meningococcal systemic disease in the infant rat model, influences neutrophil activation and endothelial injury in cell monolayer models, and is required for resistance to complement-mediated killing. The similarity of capsules such as the serogroup B ($\alpha_2 \rightarrow 8$)-linked polysialic acid and of lacto-*N*-neotetraose and other α -chain LPS structures with complex human sugars, glycosphingolipids, makes these structures infrequent targets for bactericidal antibody recognition.³⁹ Encapsulation of *N. meningitidis* down-regulates the activation of the alternative pathway and is protective against phagocytosis by human macrophages and monocytes. Sialylation of LOS in meningococci has been shown to increase resistance to classic and alternative complement-mediated killing by decreasing the deposition of C3b and IgM on the cell surface, irrespective of capsular phenotype. Phase-variable expression of the length of the gonococcal LOS or the presence of certain forms of the major outer membrane protein (Por1A) can alter levels of gonococcal susceptibility to complement killing.

SEPSIS

Septicemia remains a leading cause of death in the United States.⁴⁰ It also accounts for several billion dollars of the US's annual healthcare expenditure. Both Gram-negative and Gram-positive bacteria can trigger sepsis and septic shock (Table 24.6). Septic shock is a result of initial and widespread overstimulation of the proinflammatory response in the systemic vasculature followed by anti-inflammatory cytokine activation, and may be characterized by a number of clinical findings, including hypotension, organ failure

KEY CONCEPTS

DEFINITIONS OF SEPTICEMIA AND SEPSIS SYNDROME

- >> **Septicemia** Life-threatening bacterial infection of the bloodstream caused by Gram-positive or Gram-negative bacteria.
- >> **Sepsis syndrome** Clinical evidence of infection, plus evidence of systemic response to infection and altered organ perfusion, but may not have documented bacterial infection in bloodstream. May be due to toxin, microbial product release into bloodstream.
- >> **SIRS (systemic inflammatory response syndrome) or MODS (multiple organ dysfunction syndrome)** Response to a wide variety of clinical insults, both infectious and noninfectious (pancreatitis, burns); similar pathophysiology to septicemia and sepsis syndrome.

and death. The severity of sepsis can also be influenced by polymorphic alleles of genes involved in the inflammatory cascade.^{36–38} A related syndrome (systemic immune response syndrome, or SIRS) may be seen with the release of bacterial toxins or products from sites of colonization or local infections.

Peptidoglycan, DNA CpG motifs or LPS released by bacterial lysis or growth and toxins or superantigens are major initiators of the hypotension and shock of septicemia or SIRS, either directly through interaction with host cell membranes or indirectly through the release of host inflammatory mediators or T-cell proliferation (Fig. 24.5). The morbidity and mortality of bacteremia have been directly correlated with increased levels of proinflammatory cytokines and the amount of circulating bacterial components. Indeed, the severity of Gram-negative sepsis has been equated with high levels of endotoxin, increased levels of cytokines, and excessive activation of the alternative complement pathway. Disseminated intravascular coagulation, which often accompanies Gram-negative sepsis, is due to excessive activation of the coagulation cascade and downregulation of the fibrinolytic system associated with high levels of LPS. Levels of natural anticoagulants in the vasculature, such as antithrombin and protein C, are often low in Gram-negative sepsis. The onset and severity of DIC may be influenced by genetic polymorphisms in plasminogen activation or inhibition. The altered vascular endothelial lining facilitates thrombosis and thrombocytosis. Although much remains to be learned about the mechanisms by which Gram-negative and -positive bacteria and their products trigger sepsis, significant advances have been recently made, particularly with LPS. Advances during the past decade include the identification of certain LPS–host protein interactions that result in delivery of LPS to host cell receptors and gene activation events that result in elevated expression of a diverse array of proinflammatory mediators.

A general scheme (summarized in Fig. 24.6) for the development of endotoxic shock is as follows:

1. LPS becomes available in host fluids through rapid bacterial multiplication, release of outer membrane vesicles or the bacteriolytic action of antibiotics or antimicrobial systems (e.g., complement) in the host.

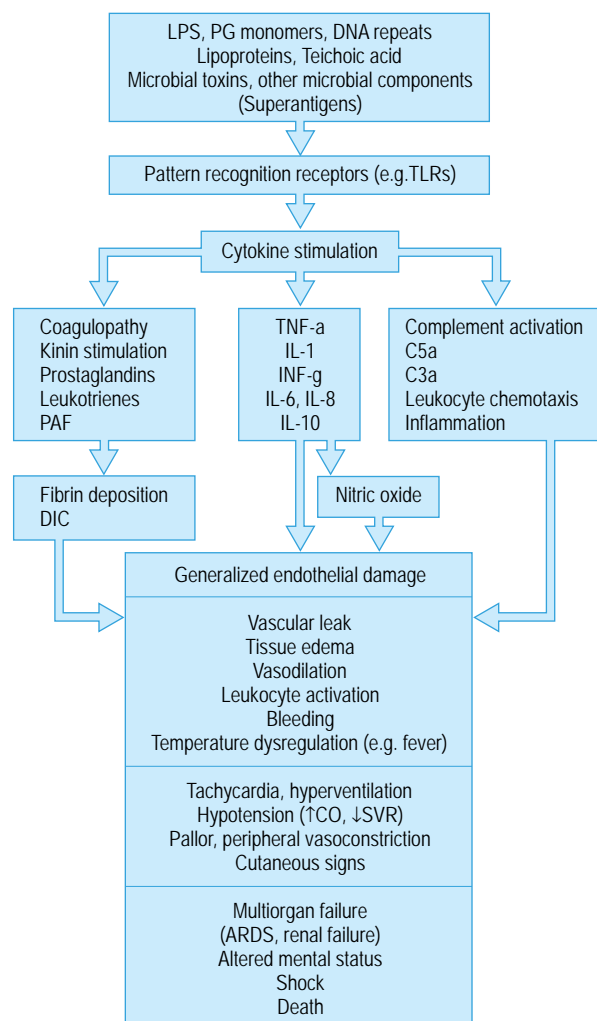

Fig. 24.5 Inflammatory cascade initiated during sepsis.

- During the acute-phase response the production of a serum glycoprotein of 60 kDa, termed lipopolysaccharide-binding protein (LBP), is increased; although structurally similar to BPI, LBP lacks bactericidal activity. LBP binds lipid A, the toxic domain of LPS, with high affinity.
- The LBP–LPS complex is then transferred to CD14, which exists in both soluble and membrane states. The primary role of LBP is to accelerate this transfer reaction.⁴¹ CD14 is clearly important in the development of endotoxic shock, as CD14-deficient mice are resistant to lethal challenge with LPS.⁴² However, membrane CD14 does not have ‘signaling’ ability. Soluble CD14 can accept LPS from the LBP complex and transfer it to an LPS receptor on the macrophage surface, which does have signaling ability.
- The nature of this LPS receptor has been defined. Poltorak et al.⁴³ ascribed the relevant genetic defect in endotoxin-resistant C3H/HeJ mice to a missense mutation in the Toll-like receptor-4 gene (*tlr4*).

TLR4 belongs to a family of transmembrane receptors originally identified in *Drosophila* as being important in controlling dorsoventral patterning and antifungal responses. TLR4 signaling requires an accessory protein, myeloid differentiation protein-2 (MD-2)⁴⁴ that binds directly to endotoxin. The key point, however, is that the LPS engagement of MD-2/TLR4 on host cells, particularly macrophages, triggers intracellular signaling events that ultimately through NF-κB and other pathways result in cytokine gene activation and the overproduction of proinflammatory cytokines (TNF-α, IL-1, IL-6, IL-8, interferons). Different TLRs (e.g., TLR2) play a critical role in the recognition of lipoproteins and the recognition of these components is a likely key determinant in the development of septic shock seen with Gram-positive infections. TLR5 recognizes bacterial flagellae, and such recognition is of likely importance in the host response to motile bacteria; some human pathogens (e.g., *H. pylori*) produce flagellin molecules that do not engage TLR5.⁴⁵ Another TLR (TLR9) has been shown to recognize bacterial DNA CpG dinucleotides.⁴⁶ Taken together, the clinical syndrome of septic shock represents a series of interactions of bacterial products with pattern recognition molecules on serum proteins (LBP and soluble CD14), and with host cell receptors (MD-2/TLR4 and TLR2, other TLR receptors) that recognize and bind bacterial products, leading to signaling events and transcriptional factors that modulate cytokine gene expression. These events trigger further events in the inflammatory cascade, leading to massive activation of the coagulation, complement and kinin pathways.

Early and effective antimicrobial therapy is the primary goal in the treatment of sepsis. Adjuvant therapy is reviewed elsewhere.⁴⁷ For example, recombinant protein C is approved for use in patients with sepsis, but is associated with an increased risk of cerebral hemorrhage.⁴⁷ In contrast to the initial phase of sepsis characterized by the release of TNF-α, IL-1, IL-6 and interferon-γ, during the latter phase an anti-inflammatory

CLINICAL RELEVANCE

SIGNS OF SEPTICEMIA

- >> Shaking chills, spiking fevers or hypothermia (<36°C)
- >> Tachycardia, hyperventilation
- >> Pallor (peripheral vasoconstriction) and acrocyanosis, but 10–20% are flushed ‘warm shock’
- >> Nausea/vomiting, diarrhea
- >> Hypotension <90 mmHg or >40 mmHg decrease from baseline, in 20–35% of cases
- >> Cardiac output, decreased systemic vascular resistance (SVR)
- >> Cutaneous signs: purpura fulminans, petechiae, palpable purpura, echthyma gangrenosum
- >> Change in mental status
- >> Signs may be more subtle in elderly and uremic (renal failure) patients
- >> WBC count >12 000/mm³ or <4000 cells/mm³ with >10% immature (band) forms
- >> Oliguria (<20 mL/h of urine)

Fig. 24.6 LPS triggering of cytokine production by macrophages. Steps known or presumed to be necessary for LPS triggering of proinflammatory cytokines.

response may predominate. The failure of anti-inflammatory therapeutic mediators (anti-endotoxin antibodies, TNF- α , antagonists of IL-1 or platelet-activating factor) in sepsis may suggest that this hypoinflammatory state encountered in many patients at presentation could be an additional target of immune modulation.

ENHANCEMENT OF IMMUNE RESPONSES TO 'EXTRACELLULAR' BACTERIA (VACCINES AND IMMUNOMODULATION)

Vaccines are the most affordable and cost-effective health intervention for enhancing the immune response to extracellular bacterial and other microbial pathogens (Chapter 92).⁴⁸ The use of vaccines to prevent diphtheria, pertussis, tetanus, certain serogroups of *N. meningitidis*, *H. influenzae* b (Hib) and *S. pneumoniae* is a major public health success. The efficacy of vaccines to extracellular bacteria is most often correlated with enhanced bactericidal antibodies, opsonic antibodies and/or neutralizing antibodies, both systemically and at mucosal surfaces. Enhancement of these immune mechanisms can provide protection even in immunocompromised individuals. For example, vaccination with meningococcal capsular polysaccharide vaccines protects patients with hereditary complement deficiencies by enhancing of opsonophagocytic activity. However, some older vaccines had limitations in terms of long-lived immune responses, safety issues, and poor responses in certain populations (extremes of age) when infections with extracellular bacteria are most common.

Advances in genetic engineering, immunology, molecular pathogenesis, vaccine adjuvants and delivery systems are leading to the development of new vaccines and vaccine approaches that enhance the immune response to extracellular bacterial pathogens. The introduction of acellular pertussis vaccines, and pneumococcal and meningococcal conjugate vaccines are recent examples.

The conjugation of bacterial polysaccharides to carrier proteins such as diphtheria or tetanus toxins has been a major advance in stimulating immune responses to saccharide bacterial antigens. Polysaccharide capsules, for example, when used alone, are 'T-independent' antigens, do not require the presence of T cells to induce an immune response, and generate IgM as the dominant antibody produced (Chapter 6). There is also a failure to induce memory and failure of affinity maturation following polysaccharide immunization. Thus, polysaccharides are poorly immunogenic in infants, the elderly, and those with impaired antibody production – groups most susceptible to encapsulated bacterial pathogens. Covalent linkage of the polysaccharide to a carrier protein converts the polysaccharide to a thymus-dependent antigen generating IgG anticapsular antibodies and memory B cells. Because these vaccines induce vigorous mucosal immune responses they also protect by herd immunity. A major (and unanticipated) result of vaccination with the *H. influenzae* (Hib), meningococcal and pneumococcal conjugate vaccines was the interruption of mucosal carriage, decreased transmission⁴⁹ and herd immunity. They are now used as part of the routine childhood and adolescent immunization series.

The presentation to CD4 T cells of an antigen by MHC class II molecules is critical for an immune response and influences the amount of antibody, the affinity of that antibody and the duration of response. The two major subsets of CD4 T cells (i.e., Th1 and Th2) influence the qualitative and quantitative features of an immune response to vaccines and bacterial antigens (Chapters 16–18). Th1 responses are characterized by complement-fixing antibody and are associated with the release of IFN- γ , IL-2 and IL-12. Th2 responses result in high circulating and secreting antibody levels and the induction of cytokines IL-4, IL-5 and IL-10.

Considerable progress is being made in the development of new vaccine adjuvants and immune modulators^{50–53} (Chapter 92). Aluminum salts, used since the 1930s in many vaccines against bacteria, induce a >90% Th2 response. As noted above, bacterial toxins as conjugates can be used to enhance immunogenicity. In addition, saponin adjuvants, liposomes, CpG DNA repeats and immunostimulating complexes are under development as adjuvants. Cytokines such as IL-1, IL-2, IL-12, IL-18 and GM-CSF also modify and enhance immune responses to vaccines.⁵³ IL-12, for example, induces strong Th1 shifts, and GM-CSF is a co-migrating signal for dendritic cells and stimulates antigen processing and presentation. Antigen recognition and processing in macrophages is critical to determining Th1 and Th2 responses and can be manipulated by selected adjuvants. Immune modulation is being evaluated not only for the enhancement of bacterial vaccines, but also as adjunct therapy for serious bacterial infections such as sepsis. Vaccines and specific immunotherapeutic approaches such as cytokines may also find use against chronic tissue-damaging inflammatory reactions created by persistent extracellular bacteria (e.g., *Helicobacter*) and autoimmune reactions that may be induced by cross-reactive bacterial antigens (e.g., *Campylobacter jejuni* and Guillain-Barré syndrome).⁵⁴

Immune responses to intracellular bacteria

Stefan H.E. Kaufmann, Helen L. Collins, Ulrich E. Schaible

25

The major driving force for evolution of the mammalian immune system is the constant encounter between the organism and its microbial invaders. The mammalian host has developed a strategy that allows for: (1) distinction of foreign invaders from self structures; (2) initial specific recognition of different intruders; and (3) subsequent mobilization of highly deleterious effector mechanisms. Despite the efficiency of this strategy, a multitude of pathogens have exploited ways to initiate infection. Even then, the host immune system may succeed in eliminating invading pathogens before disease develops, either because they are low in virulence or because the immune response is augmented. The former alternative, for example, occurs in response to vaccination with attenuated vaccine strains, the latter in vaccinees when they encounter the natural pathogen. Some invaders are attacked by the immune response soon after disease manifestation. A short, sometimes fierce struggle evolves between the infectious agent and host defense mechanisms and is decided in favor of the host or of the pathogen. This is characteristic of acute-type infectious diseases, which are caused by many purulent extracellular bacteria, including the Gram-positive and the Gram-negative cocci. Alternatively, some microbial pathogens have exploited a niche that allows them to survive in the face of an active immune response. This is the characteristic feature of intracellular bacteria, which utilize the inside of host cells as a protective recess. The immune response frequently controls replication of the pathogen but is unable to eliminate it fully. In this situation, disease is a possible consequence of infection. However, many intracellular bacteria can persist within the host for a long time, causing latent infection, and outbreak of disease is often triggered by immunocompromising conditions. It is this type of encounter between the infectious agent and the host immune system that is the focus of this chapter.

SOME FEATURES OF INTRACELLULAR BACTERIA

As indicated by the term ‘intracellular bacteria,’ the central feature of these pathogens is their intracellular existence.¹ Although many other bacteria not belonging to this group, such as *Shigella* or *Yersinia*, are also

able to invade host cells, they do so only transiently in order to invade and traverse epithelia. In contrast, intracellular bacteria in the strictest sense not only invade host cells but also permanently inhabit them and propagate within them. Intracellular living markedly influences the types of protective immune response. The intracellular niche limits contact to antibodies and nonspecific humoral effector molecules. The intracellular habitat, however, makes bacterial products accessible to intracellular processing and subsequent presentation by major histocompatibility complex (MHC) gene products. Consequently, infection is detectable by T lymphocytes. Protection of the host by T cells rather than antibodies represents a third general feature of these infections. The major task of these T cells is the activation of effective antibacterial functions in infected macrophages or, in other words, the transformation of the mononuclear phagocyte from habitat into a major effector cell. Yet frequently the macrophage does not adequately achieve this goal and some intracellular bacteria persist. At the site of the continuous struggle between activated macrophages and persistent microorganisms, granulomatous reactions develop as the characteristic tissue response, which promotes microbial containment to distinct foci. Similarly, intradermal injection of soluble antigens stimulates T cells and blood monocytes to form a transient and local tissue response – a delayed-type hypersensitivity (DTH) reaction – which serves as a useful diagnostic indicator for specific immunity against, and consequently for infection with, intracellular

CLINICAL PEARLS

Diseases caused by intracellular bacteria are often characterized by:

- >> An inability of the immune system to eliminate the organism completely: latent, persistent (sometimes dormant) pathogen
- >> The development of delayed-type hypersensitivity (DTH), which may be diagnostically useful
- >> Primarily T-cell-mediated immunity; efficacious vaccines not available thus far

bacteria. Low toxicity to the host on the one hand, and dormant persistence on the other, frequently result in symptom-free infection. Hence, disease is contingent upon, but not an inevitable result of, infection with intracellular bacteria. Moreover, diseases caused by intracellular bacteria often take a chronic course and neither pathogen nor immune response succeeds. As a final characteristic corollary of this ongoing struggle, pathology is determined by the immune response and less so by the microbe directly.

Intracellular bacteria segregate into two groups. The so-called facultative intracellular bacteria, although well adapted for living inside host cells, are also found in the extracellular space (with the probable exception of *Mycobacterium leprae*). Mononuclear phagocytes (MP) provide the preferred habitat for these bacteria, yet they are not restricted to macrophages and may infect various other host cells. This group (Table 25.1) includes the pathogenic mycobacteria *M. tuberculosis*/*M. bovis* and *M. leprae*, which are responsible for tuberculosis and leprosy, respectively,² *M. avium-intracellulare* complex and atypical mycobacteria (mycobacterial infections in the immunocompromised host),³ *Salmonella* spp. (typhoid and other salmonellosis),⁴ *Listeria monocytogenes* (listeriosis),⁵ *Legionella pneumophila* (legionnaire's disease),⁶ *Francisella tularensis* (tularemia),⁷ and pathogenic species of *Brucella* (brucellosis).⁸

The second group, the obligate intracellular bacteria, depends exclusively on the intracellular milieu and fails to grow outside cells. Although some of these bacteria may well survive in MP, they prefer other cells – the so-called nonprofessional phagocytes – particularly epithelial and endothelial cells. This group comprises the pathogenic *Rickettsia* and *Chlamydia*: *Rickettsia prowazekii* (louse-borne typhus), *R. tsutsugamushi* (scrub typhus), *R. rickettsii* (Rocky Mountain spotted fever), *Ehrlichia* sp. (ehrlichiosis), and *Coxiella burnetii* (Q fever).⁹ Different serovars of *Chlamydia trachomatis* cause urogenital and eye infections as well as trachoma and lymphogranuloma venereum, and both *C. psittaci* and *C. pneumoniae* are responsible for atypical pneumoniae (Table 25.1).¹⁰

The pathogenic mycobacteria are acid-fast bacilli that grow extremely slowly, with replication times of 12 hours and 12 days for *M. tuberculosis*/*M. bovis* and *M. leprae*, respectively.^{3,11} During chronic stages of infection and disease *M. tuberculosis* seems to be exclusively restricted to MP (Fig. 25.1), although bacteria may occasionally be found in lung parenchymal cells. In contrast, during active pulmonary tuberculosis the pathogen also multiplies in the cellular detritus of liquefied lesions. *M. leprae* is found in both MP and in various nonprofessional phagocytes, notably Schwann cells.

Salmonella typhi/*S. paratyphi*, as well as *Brucella* spp., are Gram-negative rods that not only live in macrophages of various internal organs but also in nonprofessional phagocytes such as epithelial cells. They also exist in extracellular niches, and the gallbladder provides the major source of bacterial dissemination during chronic carriage following recovery from typhoid fever. *Listeria monocytogenes*, a Gram-positive rod, is localized not only to resident tissue macrophages in spleen and liver, but also to hepatocytes.⁵ *Listeria* seem also to persist within the gallbladder of mice. Alveolar macrophages are the major habitat for *L. pneumophila*, which may occasionally disseminate to other tissue sites via MP. The pathogenic mycobacteria, *Salmonella*, *Brucella*, and *Legionella* primarily survive killing inside the phagosome by deviating from their intracellular fate, thereby interfering with macrophage effector functions (Figs 25.1 and 25.2). In contrast, *Listeria* primarily evade macrophage killing by leaving the phagosome and entering the cytoplasm.

Chlamydia undergo a distinct lifecycle: they infect host cells as elementary bodies and then develop into reticulate bodies that multiply in phagosomes and evade killing by inhibiting phagosome–lysosome fusion (Figs 25.1 and 25.2).^{10,12} Once sufficiently high numbers have been reached, they transmutate to elementary bodies ready to infect additional host cells. Columnar epithelial cells provide the preferential habitat for the different serovars of *C. trachomatis*. The lymphogranuloma venereum-causing serovars, however, do not remain in the epithelial layers and spread to lymphatic organs, where they infect endothelial and lymphatic cells. The pneumonia-causing *Chlamydia*, *C. psittaci* and *C. pneumoniae*, are typically located in lung epithelial cells.

Rickettsia are 'energy parasites,' that is, they depend on a supply of coenzyme A, NAD, and ATP from their host cells.⁹ *Rickettsia* species, preferentially inhabit vascular endothelial cells. Their virulence in entering the host cell cytoplasm to scavenge ATP also supports their escape from being killed due to phagocytosis by macrophages (Fig. 25.2). *Ehrlichia* species are zoonotic pathogens transmitted by ticks, which cause a rare disease in humans.¹³ They survive in endothelial cells and macrophages by inhibiting phagolysosome fusion. *Coxiella burnetii* preferentially parasitizes lung macrophages and parenchymal cells.¹⁴ It resists macrophage attack within acidified phagolysosomes by interfering with macrophage effector functions.

KEY CONCEPTS

CHARACTERISTIC FEATURES OF INTRACELLULAR BACTERIAL INFECTIONS

Pathogen

- >> Intracellular living
- >> Survival in phagocytes
- >> Low toxicity for the host

Immune response

- >> T-cell-dependent
- >> Antibodies less important
- >> Activated macrophages are prime effector cells
- >> Interleukin-12/-18 and interferon- γ are key cytokines
- >> Granulomatous tissue reaction (host immune-mediated)
- >> Delayed-type hypersensitivity

DISEASES CAUSED BY INTRACELLULAR BACTERIA

GENERAL FEATURES

Only a few intracellular bacteria, such as *L. monocytogenes*, are sterilely eradicated once the immune response has reached its height. More often, the intracellular habitat provides a protective niche that promotes persistent infection in the face of an ongoing immune response. In this case the bacteria can persist for long periods of time without causing clinical signs

Table 25.1 Major infectious diseases caused by intracellular bacteria

Disease	Pathogen	Transmission	Distribution	Incubation time	Preferred port of entry	Preferred target cell	Intracellular location and/or evasion mechanism	Therapy
Facultative intracellular bacteria								
Tuberculosis	<i>Mycobacterium tuberculosis</i>	Inhalation of microdroplets containing pathogen	Worldwide	Years (primary infection) Weeks (reactivation)	Lung	Macrophage Dendritic cells	Early phagosome, arrest of phagosome maturation, interference with ROI, resistance against lysosomal enzymes	Multidrug therapy including isoniazid and rifampin for 6 months
Leprosy	<i>Mycobacterium leprae</i>	Intimate contact with infected persons, nasal droplets	Southeast Asia, Africa, South and Middle America	Years	Nasopharyngeal mucosa	Primarily macrophages and Schwann cells	Phagosome, cytoplasm (?) interference with ROI, resistance against lysosomal enzymes	Multidrug therapy including dapsone, rifampin
Typhoid fever	<i>Salmonella typhi</i> / <i>S. paratyphi</i>	Contaminated food, fecal/oral	Worldwide	7–10 days	Gut	Macrophage	Phagosome, resistance to host defenses, inhibition of phagosome–lysosome fusion, interference with ROI	Chloramphenicol, trimethoprim plus sulfamethoxazole
Brucellosis	<i>Brucella</i> sp.	Zoonosis	Worldwide	Weeks to months	Respiratory tract, gut, broken skin	Macrophage	ER-associated phagolysosome, resistance to lysosomal enzymes	Tetracyclines
Legionnaire's disease	<i>Legionella pneumophila</i>	Aerosol transmission from aerosol-producing systems	Worldwide	2–10 days	Lung	Alveolar macrophage	ER-associated phagosome inhibition of phagosome–lysosome fusion, interference with ROI	Erythromycin and rifampin,
Listeriosis	<i>Listeria monocytogenes</i>	Contaminated food	Worldwide	Days to months	Gut	Macrophage, hepatocyte	Cytoplasm	Penicillin, ampicillin, co-trimoxazole

Continued

Table 25.1 Major infectious diseases caused by intracellular bacteria — Cont'd

Disease	Pathogen	Transmission	Distribution	Incubation time	Preferred port of entry	Preferred target cell	Intracellular location and/or evasion mechanism	Therapy
Obligate intracellular bacteria								
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>	Tick bite	Western hemisphere	1 week	Blood	Vascular endothelial cell, smooth-muscle cell	Cytoplasm	Tetracycline
Epidemic (louse-borne) typhus, Brill-Zinsser disease	<i>Rickettsia prowazekii</i>	Louse feces	South America, Africa, Asia	1 week	Lung, broken skin, mucosa	Vascular endothelial cell	Cytoplasm	Tetracycline
Endemic (murine) typhus	<i>Rickettsia typhi</i>	Flea bite	Worldwide	1 week	Blood	Vascular endothelial cell	Cytoplasm	Tetracycline
Scrub typhus	<i>Rickettsia tsutsugamushi</i>	Mite bite	Pacific	1 week	Blood	Vascular endothelial cell	Cytoplasm	Tetracycline
Q fever	<i>Coxiella burnetii</i>	Inhalation of aerosols, tick bite (zoonosis)	Worldwide	2–4 weeks	Lung, respiratory tract	Macrophage, lung parenchyma cell	Phagolysosome	Tetracycline
Urogenital infection	<i>Chlamydia trachomatis</i> (serovars D–K)	Sexual intercourse	Worldwide	1–3 weeks	Urogenital tract	Columnar epithelial cell	Phagosome (as reticulate body), inhibition of phagosome–lysosome fusion	Tetracycline, doxycycline, quinolone
Conjunctivitis, trachoma	<i>Chlamydia trachomatis</i> (serovars A–C)	Smear infection congenital infection	Africa	1–3 weeks (conjunctivitis), years (trachoma)	Eye	Columnar epithelial cell	Phagosome (as reticulate body), inhibition of phagosome–lysosome fusion	Tetracycline, doxycycline, quinolone
Lymphogranuloma venereum	<i>Chlamydia trachomatis</i> (serovars L1–L3)	Sexual intercourse	Asia, Africa, South America	1–3 weeks	Urogenital tract	Columnar epithelial cells, endothelia, lymphatic cell	Phagosome (as reticulate body), inhibition of phagosome–lysosome fusion	Tetracycline, doxycycline, quinolone
Pneumonia, psittacosis	<i>Chlamydia psittaci</i>	Aerosol (zoonosis), contact with infected birds	Worldwide	1–4 weeks	Lung	Macrophage, lung parenchyma cell	Phagosome (as reticulate body), inhibition of phagosome–lysosome fusion	Tetracycline
Pneumonia	<i>Chlamydia pneumoniae</i>	Aerosol (human to human)	Worldwide	1–4 weeks	Lung	Lung epithelial cells, endothelial cells	Phagosome (as reticulate body), inhibition of phagosome–lysosome fusion	Erythromycin

ROI, reactive oxygen intermediates.

(Courtesy of V. Brinkmann, Max Planck Institute for Infection Biology.)

of illness, and are reactivated to cause disease only after the immune response has become compromised. This occurs in *M. tuberculosis* infection, resulting in disease years or decades after primary contact. In fact, disease need not arise from infection at all: in many regions, for example, the majority of adults harbor *M. tuberculosis* without suffering from clinical disease. Alternatively, disease can develop directly after primary infection, during maturation of the immune response, or with regression once the immune response is sufficiently strong. Yet sterile eradication of the pathogen is rarely achieved: bacteria persist latently and illness may re-emerge at a later time. For example, *R. prowazekii* may persist for decades after convalescence from typhus, to cause Brill-Zinsser disease later.

In contrast to most intracellular bacteria, some possess components that profoundly influence the course of disease, e.g., the lipopolysaccharides (LPS) of *Brucella* and *Salmonella*. Chronic persistence inside host cells, however, depends on the target cell remaining intact and physiologically

active. Accordingly, many intracellular bacteria are of low toxicity and do not have dramatic direct effects on their host. Instead, pathogenesis is largely determined by the immune response. Classic examples of this concept include granuloma liquefaction in acute tuberculosis, which severely affects lung function, and eye scarring as a consequence of chronic or recurring *C. trachomatis* infection that ultimately leads to trachoma.

The survival of intracellular bacteria in MP has major consequences for pathology. Although many intracellular bacteria show some organ tropism, dissemination to other organs frequently occurs, resulting in different disease forms. For example, tuberculosis is generally manifested in the lung, yet any other organ can be affected. In contrast to other salmonella, *S. typhi*/*S. paratyphi* are not restricted to the gastrointestinal tract but are disseminated to internal organs, primarily the liver and spleen. In these cases the type of clinical disease depends markedly on the infected tissue type.

Fig. 25.2 Intracellular niches occupied by facultative and obligate intracellular bacteria. After particle uptake, the fate of the maturing phagosome parallels that of endosomes. After phagosome formation the vesicular membrane acquires the proton ATPase and acidifies towards pH 4–5, thereby maturing to the late endosomal and finally the lysosomal stage. *Mycobacterium* spp. and *Ehrlichia* spp. block maturation of their phagosomes early on, *Salmonella* allow slightly more maturation and *Coxiella* is delivered to the phagolysosome. On the way there, *Listeria* spp. and *Rickettsia* spp. escape into the cytoplasm, and *Legionella* spp. and *Brucella* spp. associate with membranes of the endoplasmic reticulum. *Chlamydia* spp. finally induce inclusion bodies associating with mitochondria.

SPECIFIC FEATURES

Tuberculosis

Tubercle bacilli are typically inhaled in microdroplets and then engulfed by alveolar macrophages, which transport the pathogens to the lung interstitia. There, as well as in the draining lymph nodes, primary lesions develop that rarely cause disease directly. The combination of both types of lesions is called a Ghon complex. Instead, the infection remains dormant under the control of the immune system. Once the immune response becomes debilitated, however, dormant bacteria are reactivated and pulmonary tuberculosis develops. Bacteria disseminate to other sites in the lung and occasionally to other organs, including the kidneys, liver, and central nervous system. Infection of immunocompromised patients, especially those with acquired immunodeficiency syndrome (AIDS), or newborns results in the rapid development of disease (miliary tuberculosis). Tuberculosis represents a major health problem worldwide, including an increasing incidence in many industrialized countries. In 2004, 3.9 million active tuberculosis cases were notified worldwide, and 1.7 million people died of the disease. However, as the incidence of reporting is much lower in countries where the estimated infection rate is greatest, the World Health Organization (WHO) estimates that there are in fact more than 9 million new cases globally. Yet, the much larger

estimated number of 2 billion individuals infected with *M. tuberculosis* illustrates well the dissociation of infection from disease. The emergence of multidrug-resistant strains has further complicated the situation, and a recent study has conclusively demonstrated that, following successful treatment, reinfection can occur later in life.¹⁵ The currently available vaccine bacille Calmette-Guérin (BCG), an attenuated strain derived from the agent of bovine tuberculosis, *M. bovis*, shows only low and variable protection against pulmonary tuberculosis in adults.

Leprosy

M. leprae is most likely transmitted by contact with patients who shed organisms in nasal secretions and lesion exudates. Leprosy primarily affects the nerves and the skin, frequently leading to stigmatizing deformities.¹⁶ It is a spectral disease. At the more benign tuberculoid pole, strong T-cell responses succeed in restricting microbial growth in well-defined lesions containing few bacilli. In contrast, at the lepromatous pole bacterial growth is unrestricted and lesions contain abundant bacilli within macrophages lacking signs of activation. Regulatory T cells (Treg) and other types of immunosuppression have been implicated in this latter type of disease.¹⁷ Throughout the spectrum Schwann cells are affected, promoting nerve damage and anesthesia. This results in injuries and secondary infections that significantly exaggerate the disease.

Following successful therapeutic regimens the incidence of leprosy has declined dramatically over the past decade, and in 1996 WHO estimated a global case load of 1 million with decreasing tendency.

Atypical mycobacterial infections

These environmental microbes are unable to persist within activated macrophages and thus rarely cause disease in individuals with competent immune status.³ *Mycobacterium scrofulaceum* occasionally causes lymphadenitis in children, and *M. kansasii* primarily causes infections in elderly men with pre-existing lung disease. As a consequence of human immunodeficiency virus (HIV) infection, however, nontubercle mycobacteria (NTM), primarily *M. avium*/*M. intracellulare*, have gained clinical importance, and this infection is recognized as one of the most common complications of AIDS⁶ (Chapter 37).

Typhoid or enteric fever

Typhoid is a foodborne disease caused by *S. typhi*/*S. paratyphi* in humans. The pathogens are disseminated within MP from the gastrointestinal tract to macrophage-rich organs, particularly the liver, spleen, and lymph nodes. Accordingly, typhoid is characterized by systemic symptoms such as prolonged fever and malaise with sustained bacteremia, although diarrhea or constipation may also be present. In some cases an asymptomatic carrier state can persist as a result of chronic infection of the gallbladder, which maintains the environmental reservoir of infection in endemic areas. Typhoid fever remains a major cause of morbidity and mortality, with 16 million cases and 600 000 deaths annually worldwide.

Gastroenteritis

S. typhimurium and *S. enteritidis* are the major causes of salmonella gastroenteritis in humans, which occurs mainly as a result of the ingestion of contaminated food or water. The bacteria rapidly cross the intestinal epithelia and replicate in the lamina propria, inducing an influx of polymorphonuclear granulocytes (PMN), which is generally sufficient to resolve the infection within 7 days. In rare cases the bacteria enter the bloodstream and cause systemic bacteremia, most notably in AIDS patients, where death can occur as a result of septic shock.

Brucellosis

This globally distributed zoonosis afflicts various domestic animals but is rare in humans. It is caused by *Brucella abortus*, *B. melitensis*, or *B. suis*, which primarily infect cows, goats, and pigs, respectively.⁸ The bacteria are transmitted to humans aerogenically, through abraded skin or the gastrointestinal tract. Lesions are primarily found within macrophage-rich tissues, especially the spleen and bone marrow. Human brucellosis is characterized by systemic symptoms, particularly undulant fever. Although the disease often remains subclinical, in some patients it becomes chronic, and relapses and remissions may develop.

Listeriosis

Although epidemic outbreaks of this foodborne disease have been observed, disease manifestations are most severe in patients with a compromised immune system where the central nervous system becomes

involved and fatal bacteremia can result.⁵ Additionally, as these bacteria are able to cross the placenta, listeriosis is a major cause of perinatal and neonatal disease, typically resulting in abortion. The disease is increasingly recognized, with about 2000 cases in the USA in 1992, and an incidence rate of 5 cases per million population.

Legionnaire's disease or legionellosis

Legionnaire's disease is caused by *Legionella pneumophila*, an environmental bacterium that persists within amoeba living in water reservoirs (e.g., air-cooling systems), from where it is spread aerogenically.⁶ Infection is exacerbated by a compromised immune status. Characteristically, legionnaire's disease presents as atypical pneumonia associated with general symptoms and complicated by extrapulmonary infection, renal failure, and lung abscesses.

Lymphogranuloma venereum

Lymphogranuloma venereum, a sexually transmitted disease, is highly prevalent in Africa, Southeast Asia, and South America. It is caused by the L1, L2, and L3 serotypes of *Chlamydia trachomatis*, which are disseminated from the urogenital tract to local lymph nodes and then to the skin. Accordingly, lymphogranuloma venereum is characterized by lymph node swelling and skin lesions that are accompanied by systemic complications.

Chlamydial urethritis, cervicitis, and conjunctivitis

C. trachomatis serovars D–K remain in epithelial cells of the urogenital tract, causing cervicitis and urethritis. In women, infertility may develop as a result of chronic or recurrent infection. In neonates, congenital infection during birth may result in conjunctivitis and pneumonia. Urogenital infections by *Chlamydia* occur worldwide and are now considered to be the most common bacterial sexually transmitted disease, with an estimated 90 million new infections occurring annually.¹²

Trachoma

Smear infections of the eye with *C. trachomatis* serovars A, B, and C cause inclusion conjunctivitis.¹⁰ As a consequence of multiple chronic infections and of the resulting immune response, scars develop that eventually injure the cornea, leading to trachoma. It is estimated that 400–600 million people suffer from *C. trachomatis* infection, and 6 million of these suffer visual impairment worldwide.

Chlamydia pneumoniae

C. pneumoniae (formerly known as *C. trachomatis* TWAR strain) is the cause of mild respiratory disease in young adults and may cause serious infections in older, more debilitated patients. Atypical pneumonia may also be caused as a result of infection with *C. psittaci*, although this zoonosis is relatively rare.

Typhus

Rickettsia prowazekii, *R. typhi*, and *R. tsutsugamushi* cause diseases of varying severity.⁹ They are transmitted by arthropods and infect vascular endothelial cells at the site of an insect bite or scratch, causing skin reactions.

Subsequently, pathogens are disseminated to the central organs and more general symptoms develop. Globally, typhus is of minor importance.

Rocky Mountain spotted fever, ehrlichiosis

Rocky Mountain spotted fever is caused by *R. rickettsii*. Infection of the vascular endothelium leads to systemic symptoms and skin manifestations that may be followed by shock and neurological complications.⁹ Worldwide, this disease, as well as Mediterranean spotted fever caused by *R. conorii*, is of minor importance, as is probably ehrlichiosis, a newly emerging zoonosis transmitted by ticks and caused by various *Ehrlichia* species, mainly *E. chaffeensis*.¹³ Disease manifestations include generalized symptoms such as fever and muscle pain.

Tularemia

This rare zoonosis in humans, caused by *Francisella tularensis*, is mainly found in rabbits and has recently gained wider recognition due to its potential for dual use.⁷ This Gram-negative bacterium survives in macrophages and primarily causes acute pneumonia as well as sores of the skin, with subsequent involvement of the lymph nodes.

THE IMMUNE RESPONSE AGAINST INTRACELLULAR BACTERIA

INNATE IMMUNITY

The innate immune response is a rapid and largely nonspecific reaction that coordinates the initial response to pathogens (Chapter 3). It depends critically on the ability of cells – primarily MP and dendritic cells (DC) – to recognize a broad variety of pathogens. This is accomplished by their ability to discriminate between molecules synthesized exclusively by bacteria such as LPS, bacterial lipoproteins and lipoteichoic acids, and self molecules. Phagocytic cells possess a set of germline-encoded pattern recognition receptors (PRR) that recognize invariant molecular patterns shared by a variety of microbes, the so-called pathogen, or better, microbe-associated molecular patterns (PAMP or MAMP). These receptors include the macrophage mannose receptor (MMR), DC-specific ICAM-3-grabbing nonintegrin (DC-SIGN) both of which bind mannose residues, dectin 1 (binds β -glucans), CD14 (binds LPS, lipoarabinomannan (LAM)), scavenger receptors (SR-A, SR-B), CD36 (binds microbial diacyl glycerides), and the Toll-like receptors (TLR).^{18, 19} It has been suggested that, whereas PRR are required to bind and internalize the pathogen, it is the TLR that discriminate between the pathogens and provide the necessary intracellular signaling events. It should, however, be noted that intracellular signaling events can also be triggered by ligand binding to MMR, dectin 1, or DC-SIGN. Intracellular PRR include NOD-1 and -2-recognizing bacteria-derived muramyl dipeptides or diaminopimelic acid, respectively.²⁰ The TLR system appears as an innate scanning mechanism for microbial patterns to recognize and distinguish between a wide array of microbes, i.e., bacteria, viruses, parasites, and fungi. TLR are present as homo- or heterodimers on the plasma membrane or within endosomes/phagosomes (Fig. 25.3).^{18, 21} TLR ligands of bacterial origin comprise di- and tri-acylic lipoproteins, LPS, and flagellin, which are recognized

by TLR-2/6, TLR2/1, TLR-4/4, or TLR-5/5, respectively. The vast array of mycobacterial cell wall lipids such as LAM, trehalose dimycolate (TDM), and phosphatidyl inositol mannosides (PIM) bind either TLR-2 or TLR-4. Lipoteichoic acid (LTA) of Gram-positive bacteria is recognized by TLR-2. TLR-9 binds low methylated bacterial DNA containing CpG motifs within endosomes (Fig. 25.3). Ligand binding to TLR initiates an inflammatory response, including release of proinflammatory mediators.²¹

Binding of a bacterium to certain host receptors leads to the active internalization of the organism, a prerequisite for an intracellular pathogen. Only professional phagocytes such as MP and PMN perform this host-directed process. Direct binding to a receptor is frequently supported indirectly by complement components and immunoglobulin, which bind to complement receptors and Fc receptors, respectively. Uptake via specific receptors is called the ‘zipper mechanism,’ which distinguishes it from internalization resulting from nonspecific adhesion, known as the ‘trigger mechanism.’ In some cases intracellular bacteria can exploit nonprofessional phagocytes, which provide a less hostile environment owing to their inability to mobilize antibacterial effector mechanisms. Vascular endothelial cells, epithelial cells, Schwann cells, and hepatocytes are the preferred habitats for *Rickettsia* spp., *C. trachomatis*, *M. leprae*, and *L. monocytogenes*, respectively. These host cells express minimal phagocytic activity, thereby necessitating that the bacteria induce their own internalization. This invasion process requires tight adhesion to specific cellular receptors that are capable of mediating the uptake process, including members of the integrin and growth factor receptor families. The tight binding of bacteria to these receptors activates the intracellular cytoskeleton to cause macropinocytosis, i.e., membrane ruffling, invagination, and finally phagosome formation.⁴

NATURAL KILLER CELLS

Natural killer (NK) cells were originally characterized by their capacity to lyse susceptible tumor cells in an MHC-independent fashion. They are large granular lymphocytes identified by the CD56 marker. Several lines of evidence indicate a contribution of NK cells to antibacterial resistance.²² As NK cells express functions also performed by T lymphocytes, they contribute to early host defense before the appearance of activated T cells in normal individuals (Chapter 18). They may also fulfill an important compensatory role in T-cell-deficient patients.

Incubation of peripheral blood leukocytes from healthy individuals with a variety of intracellular bacteria induces potent NK-cell activity *in vitro*. Furthermore, infection of mice with various intracellular bacteria causes strong NK-cell activation *in vivo*. NK cells have been shown to lyse host cells infected with various intracellular bacteria, including *Legionella*, *Mycobacteria*, *Salmonella*, *Chlamydia*, and rickettsiae.²² Moreover, NK cells are potent interferon- γ (IFN- γ) producers, thus contributing to macrophage activation (Fig. 25.4). Severe combined immunodeficiency disease (SCID) mice, which are virtually free of functionally active T and B cells, are able to control experimental listeriosis due to enhanced NK-cell activity as a compensatory mechanism. However, they are unable to eradicate the bacteria completely, and ultimately succumb to disease. To date, the exact mechanism as to how NK cells distinguish infected from uninfected cells has not been elucidated. NK cells possess two types of surface receptors. One group comprises “activating” receptors such as NKp30, NKp46, and NKG2D, which trigger killing by NK cells, whereas others inhibit cytotoxicity.²³ Of the

Fig. 25.3 Toll-like receptors (TLR) and nucleotide-binding oligomerization domain (NOD) are innate pattern recognition receptors (PRR) for microbe-associated molecular patterns (MAMP). As distinct homo- or heterodimers at the plasma membrane or within endosomes they recognize bacterial glycolipids, polysaccharides, lipopeptides, flagellins, and low methylated DNA (CpG). NODs are cytoplasmic receptors for the bacterial degradation products muramyl dipeptide (MDP) derived from peptidoglycan and diaminopimelic acid (DAP).

activating receptors NKp30, NKp46, and NKG2D, the latter two are induced by macrophages infected with *M. tuberculosis* and mediate NK-cell-mediated killing of infected target cells. Some of the inhibitory receptors recognize MHC class I molecules. Thus, NK cells specifically lyse target cells expressing low levels of MHC class I molecules, and therefore a possible recognition mechanism would be alteration in MHC class I expression. Notably, surface expression of MHC molecules on macrophages is often reduced as a consequence of bacterial infection.

MACROPHAGE ACTIVATION AND EFFECTOR MECHANISMS

Both MP and PMN represent major effector cells in the defense against bacterial infections. PMN are within the first line of defense and efficiently kill microbial invaders, thus contributing to limiting the size of inoculum. Lack of PMN strongly enhances susceptibility to fast-growing *Listeria* and *Salmonella*. However, because of their short lifespan, PMN are an inappropriate habitat for intracellular bacteria, particularly for slow-growing ones.²⁴ Against such bacteria, the highly antimicrobial potential of PMN also appears to be of low effect. In general, intracel-

lular bacteria are often less accessible to PMN because of their location inside cells. PMN, however, due to succumbing to apoptosis within less than 1 day of their lifespan, may be exploited by intracellular pathogens as 'Trojan horses' in order to enter macrophages unrecognized and unwrapped within apoptotic bodies from dying PMN.²⁵ In contrast, tissue macrophages have a long lifespan and, in their resting stage, possess only medium antimicrobial potential. Resting tissue macrophages therefore serve as a suitable habitat for numerous intracellular bacteria (Fig. 25.2). Activation by cytokines leads to the mobilization of various antibacterial effector mechanisms, thus transforming MP from residence to effector cell (Table 25.2). Yet intracellular bacteria are able to counteract assaults by activated macrophages, at least partially, by evading, interfering with, or resisting their effector mechanisms.

The transition from resting to activated macrophage is a multifactorial and highly regulated process involving the induction of interleukin-12 (IL-12), IL-18, and related cytokines (IL-23, IL-27) by TLR ligands (Fig. 25.4). This in turn stimulates the production of IFN- γ from NK cells, which subsequently promotes development of Th1 T cells. Thereby, production of IFN- γ , the central macrophage-activating cytokine, is perpetuated, ultimately leading to tumor necrosis factor- α (TNF- α)

Fig. 25.4 Preferential Th1-cell activation in intracellular bacterial infections. Although in intracellular bacterial infections the activation of macrophages by interferon- γ (IFN- γ) from Th1 cells is the predominant event, this step is influenced by numerous other cytokines. Natural killer (NK) cells are the first cells upon microbial encounter to secrete IFN- γ . In terms of Th1-cell stimulation, interleukin-12 (IL-12), IL-18, and IFN- γ provide activating signals, whereas the Th2-derived cytokines IL-4 and IL-10 are inhibitory. At the level of macrophages (MP), IFN- γ , produced first by NK cells and NKT cells and later on by antigen-specific T-cell subsets, promotes the development of Th1 cells and MP activation. Th17 cells promote inflammation through IL-17 secretion and neutrophil activation. Regulatory T cells (Treg) dampen inflammation through IL-10 and/or transforming growth factor- β (TGF- β) secretion in order to minimize immunopathology. IL-10 also counteracts macrophage activation. DN represents double-negative (CD4⁻ CD8⁻) T cell.

secretion (Fig. 25.4 and Table 25.2). However, IFN- γ production and macrophage activation are inhibited by microbial components such as phenolic glycolipid from *M. leprae*, as well as by anti-inflammatory cytokines such as IL-4, IL-10, and TGF- β .¹⁷ Although these cytokines can be produced by various cell types, including DC, macrophages, B cells, NK T, and Th2 cells, Treg (CD25⁺/FOXP3⁺) have been identified as the prime players in controlling IFN- γ -mediated responses (see below). Mechanisms to counter-regulate IFN- γ function can limit exacerbated inflammation and immunopathology.

Once fully activated, MP are capable of killing most microbial pathogens, including certain intracellular bacteria. Only the most resistant bacteria, such as *M. tuberculosis*, are not fully eliminated, in which case persistent organisms may emerge. Activated macrophages not only express antimicrobial activities, they also secrete biologically active components that significantly influence the outcome of disease (Table 25.2). First, they release proteolytic enzymes that contribute to local tissue destruction; second, they secrete cytokines that regulate phagocyte attraction, granuloma formation, and macrophage activation.

Bacterial killing by toxic reactive nitrogen intermediates (RNI) and reactive oxygen intermediates (ROI)

Activation of a membrane-bound NADPH oxidase by stimulation with IFN- γ or IgG initiates an oxidative burst that generates the toxic ROI, O₂⁻, H₂O₂, OH⁻, ¹O₂, and 'OH radical (Table 25.2).²⁶ In human PMN and blood monocytes that possess myeloperoxidase, the ROI activity is further supported by the formation of hypochlorous acid. Oxidation and/or chlorination of bacterial lipids and proteins result in the death of many bacteria. The importance of ROI in antibacterial defense is underlined by the recurrent infections in patients whose phagocytes fail to generate an oxidative burst (Chapter 21). Production of RNI from activated murine macrophages generated by inducible nitric oxide synthase (NOS-2 or iNOS) is well established (Table 25.2).²⁷ Expression of NOS-2 has also been detected in monocytes of patients suffering from a variety of infectious diseases. The 'NO radical is generated exclusively from L-arginine and then further oxidized to NO₂⁻ and NO₃⁻. The formation of 'NO is catalyzed by

Table 25.2 Antibacterial effector mechanisms of activated macrophages and microbial evasion strategies

Macrophage effector mechanism	Microbial evasion strategy
Production of reactive oxygen intermediates (ROI)	Uptake via complement receptors Production of ROI detoxifying molecules (superoxide dismutase, catalase) Bacterial ROI scavengers (e.g., phenolic glycolipids, sulfatides, lipoarabinomannans)
Production of reactive nitrogen intermediates (RNI)	Inhibition of phagosome maturation Most ROI detoxifiers also affect RNI
Other types of intraphagolysosomal killing	Evasion into the cytoplasm Robust cell wall resistant to low pH / lysosomal hydrolases
Phagosome acidification Phagosome–lysosome fusion	Prevention of phagosome maturation by bacterial components, e.g., glycolipids
Defensins	Modification of cell wall lipid A
Reduced iron supply (transferrin receptor downregulation, lipocalins)	Microbial siderophores
Tryptophan degradation	Affects <i>Chlamydia</i> sp., other bacteria upregulate endogenous tryptophan synthesis

NOS-2, which is stimulated by both immunological stimuli such as IFN- γ and TNF, and microbial products such as LPS, LTA, and mycobacterial lipids. The RNI exert their bactericidal activity by destroying iron-/sulfur-containing reactive centers of bacterial enzymes, and by synergizing with ROI to form highly reactive peroxynitrite (ONOO⁻).

Tryptophan degradation

Deprivation of required nutrients appears to be an obvious strategy for microbial killing, yet it seems to be employed rarely, with restricted tryptophan supply being the best-known example. Tryptophan degradation is achieved by the enzyme indolamine 2,3-deoxygenase, which degrades tryptophan to kynurenine (Table 25.2). This reaction is induced by IFN- γ in both MP and IFN- γ -responsive nonprofessional phagocytes and inhibits the growth of *C. psittaci* and *C. trachomatis* inside human macrophages and epithelial cells.²⁸

Antimicrobial peptides

Defensins and basic proteins are small lysosomal polypeptides that are microbicidal at basic pH and are particularly abundant in phagocytes.²⁹ Many of these compounds have been shown to have microbicidal activity against intracellular bacteria, particularly granulysin, which is present in the granules of human NK and cytolytic T cells. This molecule kills a number of pathogens *in vitro*, including *L. monocytogenes* and *S. typhimurium*, as well as intracellular *M. tuberculosis*.³⁰ Another antimicrobial peptide, cathelicidin, is modulated by vitamin D in a TLR-2 dependent manner to kill *M. tuberculosis*.³¹

Intracellular iron

Iron is required for many biochemical processes in both prokaryotes and eukaryotes. In light of this, competition between host cell and pathogen is established for the intracellular iron pool. Both cell types,

therefore, possess specific iron-binding proteins that promote the uptake and intracellular distribution of iron.³² Extracellular iron is bound to transferrin and lactoferrin and is internalized by the transferrin receptor into an early recycling compartment, whose mildly acidic pH permits the uncoupling of iron from its receptor. Within the host cell most of the iron is bound to ferritin. Intracellular bacteria such as mycobacteria, *Brucella*, and *Chlamydia* have evolved a number of iron-binding proteins or siderophores which are upregulated in the intracellular environment. As countermeasures, activated macrophages downregulate surface expression of the transferrin receptor to limit intracellular iron (Table 25.2). Moreover, PMN-derived lipocalins bind bacterial siderophores, including those from mycobacteria to seclude iron from microbial usage.

MICROBIAL EVASION FROM, INTERFERENCE WITH, AND RESISTANCE TO MACROPHAGE KILLING

Strategies against toxic effector molecules

Many intracellular bacteria have exploited successful strategies against macrophage effector molecules (Table 26.2). One mechanism is determined by the receptor that is used for pathogen entry into the host cell. Internalization via complement receptors inhibits the production of IL-12, a cytokine critical in facilitating macrophage activation.³³ Engulfment by this receptor also bypasses activation of the oxidative burst, thereby avoiding ROI production. Similarly, engaging MMR and DC-SIGN for uptake triggers IL-10 and TGF- β secretion. Several intracellular bacteria also produce ROI detoxifiers, including superoxide dismutase and catalase, which nullify O₂ and H₂O₂, respectively. Finally, a number of small bacterial products, such as the phenolic glycolipid and LAM of mycobacteria, scavenge ROI. Many of the strategies used to counteract the effects of ROI also overlap in their effects on RNI. A modification

of lipid A renders Gram-negative bacteria, including *Salmonella*, resistant to the effects of host antimicrobial peptides.²⁹

Intraphagosomal survival

Inhibition of phagolysosome fusion represents a major intracellular survival strategy for a number of intracellular bacteria, including *M. tuberculosis*/*M. bovis*, *S. typhi*/*S. paratyphi*, *L. pneumophila*, and *C. trachomatis* (Fig. 25.2). The inclusion body formed following phagocytosis of *Chlamydia* is excluded from the classic pathway of phagosome maturation and forms tight associations with mitochondria that provide a rich source of ATP.¹⁰ In contrast, mycobacteria arrest maturation of this compartment at an early endosomal stage. This compartment does not acidify owing to a paucity of vacuolar H⁺ATPase; at the same time, it exchanges molecules with the plasma membrane such as the transferrin receptor to access iron.³⁴ The exact mechanism as to how mycobacteria influence phagosome maturation remains unclear and various suggestions have been made, such as the production of ammonia or cell wall glycolipids and their physicochemical properties. What is clear is that activation of MP with IFN- γ restores maturation of the mycobacterial phagosome, resulting in a drop in mycobacterial viability. *Salmonella* species express two secretion apparatus in order to inject effector molecules into the host cell cytoplasm to achieve invasion and intracellular survival. These effectors induce cytoskeleton rearrangements in the host cell to macropinocytose the bacteria and promote phagosome arrest at an early to late endosomal stage (Fig. 25.2). Finally, *Legionella* and *Brucella* after a transient phagosomal stage enter compartments enclosed by endoplasmic reticulum (ER) membranes, suggested to resemble autophagosomes, to escape delivery to phagolysosomes.³⁵

Escape into cytoplasm

A successful strategy for survival inside activated macrophages is the egression from the phagosome into the cytoplasm, which has been exploited by *L. monocytogenes* and the various pathogenic *Rickettsia* species (Fig. 25.2 and Table 25.2). This has the advantage of both avoiding the cellular defense mechanisms within the phagosome and providing the bacteria with a nutrient-rich environment. *Listeria monocytogenes* possesses several virulence factors to facilitate its escape from the phagolysosome, a pore-forming hemolysin (listeriolysin, LLO) which acts together with a metalloproteinase, a lecithinase, and two phospholipases to promote the rupture of the phagosomal membrane efficiently, as well as spreading to other cells.³⁶

Cell-to-cell spreading

For a bacterial pathogen that is very well adapted to the intracellular milieu and vulnerable to extracellular defense mechanisms, it is highly desirable to remain within host cells. Yet once a sufficiently high number of bacteria has been reached, the original cell dies and bacteria are released into the extracellular space. To avoid this fate, however, some intracellular bacteria have developed mechanisms that allow their direct spreading to other cells. *L. monocytogenes* induces polar actin polymerization by means of a surface protein, ActA. A polymerized actin tail is formed which pushes the bacteria through the cell, forcing the host cell membrane to protrude into a neighboring cell. This cell engulfs this protrusion, and eventually

both the new membrane and the host membrane are dissolved by phospholipases.³⁶

■ ACQUIRED IMMUNITY ■

The adaptive immune response critically depends on the recognition of foreign antigens that are degraded to peptides and then presented to T cells in the context of MHC molecules on the surface of antigen-presenting cells (APC), including macrophages and DC.

T LYMPHOCYTES AS SPECIFIC MEDIATORS OF ACQUIRED RESISTANCE

Whereas activated macrophages act as the nonspecific executors, T lymphocytes are the specific mediators of acquired resistance against intracellular bacteria. The dramatic increase in the incidence of tuberculosis and other intracellular bacterial infections in AIDS patients well illustrates the central role of T lymphocytes. For instance, at least 0.5 million individuals are coinfecting with HIV and *M. tuberculosis*. HIV increases the risk of developing tuberculosis by several orders of magnitude. At the site of microbial growth, T lymphocytes not only initiate the most potent defense mechanisms available, they also focus this response to the site of encounter, thus minimizing detriment to the host. Although protective T-cell responses are multifactorial, they can be reduced to a few principal mechanisms (Fig. 25.4).

T cells inevitably also produce pathology, and the pathogenesis of infections with intracellular bacteria is significantly determined by T cells. It is therefore important that the T-cell response be tightly controlled and can be downregulated when necessary. Regulatory mechanisms, which are executed by a number of cells, including Treg cells, are in place to limit immunopathology.

Protective immunity involves conventionally defined T-cell sets, CD4 $\alpha\beta$ T cells, and CD8 $\alpha\beta$ T cells, as well as unconventional T cells such as $\gamma\delta$, CD1-restricted $\alpha\beta$ T cells, and nonclassical MHC class I-restricted $\alpha\beta$ T cells (Fig. 25.4). Although these T-cell sets perform different tasks, substantial redundancy exists. Furthermore, these T-cell populations act not independently, but in a coordinated way and in close interaction with other leukocytes, such as NK cells.²²

■ KEY CONCEPTS

T-CELL-MEDIATED MECHANISMS UNDERLYING PROTECTION

- >> Activation of macrophages via cytokine secretion (especially interferon- γ)
- >> Lysis of infected target cells
- >> Bacterial killing
- >> Attraction of effector cells from blood to tissue sites
- >> Formation and maintenance of granulomatous lesions
- >> No sterile eradication

Fig. 25.5 Pathways of antigen processing and T-cell activation. Antigens from phagosomal bacteria and their proteins secreted into the phagosome are presented by major histocompatibility (MHC) class II molecules to CD4 T cells. MHC class II molecules pick up antigenic peptides within late endosomes, termed lysosomes. Somatic and secreted proteins from bacteria within the cytoplasm are presented by MHC class I molecules to CD8 T cells. MHC class I molecules pick up antigenic peptides in the endoplasmic reticulum (ER) imported from the cytoplasm through TAP transporters and processes by proteasomes and other cytoplasmic and ER/Golgi-resident proteases. As a third pathway, cross-presentation through apoptotic blebs from infected cells going into programmed cell death facilitates presentation of antigens from phagosomal bacteria by MHC class I and MHC II to activate both CD4 and CD8 T cells.

Depending on the etiologic agent and the stage of disease, the relative contribution of the different T-cell subsets to acquired resistance may vary. The conventional $\alpha\beta$ T cells make up more than 90% and $\gamma\delta$ T cells make up less than 10% of all lymphocytes in the blood and peripheral organs of humans and mice. However, $\gamma\delta$ T cells represent a significant proportion of the intraepithelial lymphocytes in mucosal tissues, suggesting a particular role at this important port of microbial entry (Chapter 19). Implication of all T-cell populations is primarily derived from studies with experimental animals and immunohistological *in-situ* hybridization studies of lesions.

CD4 T cells

The central role of CD4 T cells in immunity to intracellular bacteria is unquestioned (Fig. 25.4). Overwhelming evidence from experimental animal studies, their abundance in “protective” granulomas of patients suffering from bacterial infections, and the high prevalence of disease caused by intracellular bacteria in CD4 T-cell-deficient AIDS patients all support the salient role of CD4 T cells. Such T cells recognize antigenic peptides in the context of MHC class II molecules. MHC II molecules pick up antigenic peptides within the endosomal system (Fig. 25.5). Thus, antigens from all intracellular bacteria, even those that evade the phagosome at later stages, are accessible to processing and presentation through the MHC class II pathway. A potential drawback of CD4 T cells is related to their failure to recognize infected cells that

are constitutively MHC class II-negative. These include endothelial cells, epithelial cells, hepatocytes, and Schwann cells, the potential targets of *Rickettsia* spp., *C. trachomatis*, *L. monocytogenes*, and *M. leprae*, respectively.

The CD4 T-cell population can be further subdivided into two distinct subsets, according to their pattern of cytokine production: Th1 cells, which produce IFN- γ and TNF- β , and Th2 cells which produce IL-4, IL-5, IL-6, and IL-13 (Chapter 17). In light of this, there are differences in the host immune system induced by these T-cell sets. IFN- γ from Th1 cells promotes cell-mediated immunity, characterized by macrophage activation, stimulation of cytolytic CD8 T cells, and the production of opsonizing IgG antibodies. In contrast, Th2 cells control the differentiation of B cells and promote Ig class switching to IgE and IgA, and are subsequently responsible for protection against helminth infections as well as promoting allergic responses. The development of both T-cell subsets from a common precursor Th0 cell is under the regulation of distinct cytokines. IL-12 and IL-18, secreted by macrophages and DC, in addition to NK-cell-produced IFN- γ , promote the development of Th1 cells, whereas IL-4 is responsible for the development of Th2 cells, although the cell type responsible for the initial production of this cytokine is still under debate. NK T cells, a T-cell subpopulation expressing an evolutionary conserved TCR, which arises rapidly after infection to secrete both IFN- γ and IL-4, could be involved here (Fig. 25.4).^{37,38}

A distinct Th-cell population secretes vast amounts of IL-17, a characteristic which gave this population the term Th17 cells. Cytokines of

the IL-17 family are strong inducers of granulopoiesis, of proinflammatory mediators such as IL-6, and of the chemokines CXCL1, CXCL8, and CXCL6 to attract neutrophilic and eosinophilic PMN and prolong their survival.³⁹ Although Th17 cells are primarily suggested to be responsible for uncontrolled inflammation in allergic and autoimmune reactions, a function in antibacterial immunity both in protection as well as in immunopathology is likely. These cells seem to be particularly important for infection control in the lung.

In general, experimental infections with intracellular pathogens induce a Th1 response that is protective. There is now evidence that the Th1/Th2 dichotomy also exists in humans, and this is best exemplified by the host response to *M. leprae* infection. Here, the tuberculoid form of the disease is characterized by a Th1-type reaction resulting in activated macrophages and effective granuloma formation with few detectable bacilli. In contrast, towards the lepromatous end of the disease spectrum, an abundance of organisms and poor granuloma formation are associated with the production of IL-4, IL-10, and IL-13 (although it should be noted here that in this situation it is CD8 T cells that are the predominant cytokine producers).

CD8 T cells

Infection of mice deficient in specific T-cell subsets has conclusively demonstrated a role for CD8 T cells in *Listeria* infections. More recently, these observations have been extended to include tuberculosis.⁴⁰ Furthermore, CD8 effector T cells have been identified in "protective" granulomas of tuberculoid leprosy patients. The cytolytic potential of these T cells can serve two roles in infection, namely target cell killing, which results directly in the inhibition of the growth of bacteria; or the lysis of cells that are unable to control the infection, thus releasing the bacteria for phagocytosis by more activated cells. Recently it has been demonstrated that populations of CD8 T cells can indeed lyse cells, resulting in a reduction in growth of *M. tuberculosis*. This microbicidal mechanism is mediated by granulysin, which is introduced into the target cell via a perforin-generated pore.³⁰ CD8 T cells are also a potent source of IFN- γ , and thus contribute to protective mechanisms (Fig. 25.4).

CD8 T cells recognize antigenic peptides in the context of MHC class I gene products. Initially, therefore, it was mysterious how these CD8 T cells were stimulated by intracellular bacteria, which were thought to have a uniquely restricted phagosomal residence. However, with the knowledge that many intracellular bacteria such as *L. monocytogenes* invade the cytoplasm, one major mechanism for MHC class I processing became obvious: proteins secreted by bacteria in the cytoplasm undergo antigen processing and presentation similarly to newly synthesized host proteins (Fig. 25.5).³⁶ However, even antigens from intracellular bacteria such as *S. typhimurium* and *M. tuberculosis*, which remain in the phagosome, are presented to CD8 T cells.⁴¹ Hence, alternative contact points for MHC class I molecules and bacterial peptides need to be assumed. Cross-presentation by noninfected APC of antigens engulfed together with apoptotic blebs from infected cells represents a critical pathway to induce CD8 T cells by phagosomal bacteria (see below). One major advantage of CD8 T cells over CD4 T cells is their recognition of antigen bound by MHC class I gene products, which are expressed by almost all host cells. Thus, CD8 T cells recognize professional and nonprofessional phagocytes equally well.

Cross-presentation

Many intracellular bacteria such as *Chlamydia* and *Rickettsia* dwell within nonprofessional APC, which do not expose MHC II in appreciable amounts and lack expression of co-stimulatory molecules.⁴² Those living inside professional APC, such as *Salmonella* and mycobacteria, interfere with expression of antigen-presenting molecules in general, thereby inhibiting T-cell activation. Mycobacteria are secluded from the classical cytoplasmic MHC I processing pathway within tight phagosomes. Despite these hindrances, basically all intracellular bacteria induce CD4 and CD8 T cells. Cross-presentation by noninfected APC is probably responsible for this phenomenon, at least in tuberculosis and salmonellosis.⁴³ Noninfected cells engulf bacterial antigens enwrapped within apoptotic bodies and blebs thereof, when infected cells succumb to programmed cell death. Apoptosis as a prerequisite for this pathway is induced by many intracellular bacteria, including *Salmonella*, mycobacteria, and even those escaping the phagosome, i.e., *Listeria*. For example, only *Salmonella* strains, which also induce apoptosis, elicit CD8 T cells. This cross-presentation pathway in infections with intracellular bacteria adds an essential function to the physiological role of apoptosis in maintenance of tissue integrity and growth.

$\gamma\delta$ T CELLS

The relevance of the $\gamma\delta$ T-cell set to bacterial immunity is less well understood. $\gamma\delta$ T cells produce cytokines and are cytolytic; hence they cover a functional spectrum similar to that of their $\alpha\beta$ T-cell counterparts (Fig. 25.4).⁴⁴ Although the genetic restriction of antigen recognition by $\gamma\delta$ T cells is incompletely understood, it is clear that they are less fastidious than $\alpha\beta$ T cells in this respect. Hence, in principle, all infected host cells are potential targets for $\gamma\delta$ T cells. Experimental mouse studies revealed the early accumulation of $\gamma\delta$ T cells at sites of bacterial deposition. $\gamma\delta$ T cells have also been identified in certain forms of disease, including tuberculous lymphadenitis and leprosy lesions during reactional stages. Because of their less demanding activation and antigen recognition requirements, $\gamma\delta$ T cells may fill a gap between nonspecific resistance and the more specific $\alpha\beta$ T-cell response. Furthermore, transient participation of $\gamma\delta$ T cells in protection and a unique requirement for $\gamma\delta$ T cells in granuloma formation have been described for experimental listeriosis and tuberculosis infection in mice. In mice, antigens recognized by $\gamma\delta$ T cells appear to comprise heat shock protein-derived peptides presented by nonpolymorphic MHC class I molecules. In contrast, human $\gamma\delta$ T cells respond to small nonproteinaceous phosphate-containing compounds of bacterial origin.

T cells controlled by CD1 molecules

CD1 comprises a group of nonpolymorphic MHC-related molecules that can present glycolipid antigens to unconventional T cells (Fig. 25.4). They are divided into two groups. In humans, T cells that respond to group I CD1 molecules, i.e. CD1a, b, and c, are either CD4/CD8, CD4 or CD8 and express the $\alpha\beta$ TCR. These cells can respond to a variety of microbial glycolipids, including LAM, PIM, mycolic acids, sulfatides, sulfoglycolipids, lipopeptides, and isoprenoids derived from mycobacteria.⁴⁵ Upon antigen stimulation these T cells can proliferate and secrete IFN- γ , as well as lyse macrophages infected with mycobacteria. The group II CD1 molecule CD1d, the only CD1 molecule found in mouse and rat, controls development of NKT cells that express both the

NK-cell marker NK1.1 and an invariant evolutionary conserved TCR. Upon antigen activation these T cells rapidly produce cytokines and are capable of producing both IL-4 and IFN- γ . As bacterial antigens recognized by NKT cells, PIM from mycobacteria and glycosphingolipids from *Ehrlichia* and *Sphingomonas* species have been identified so far.

Memory T cells

Similar to other infectious agents, protective immunity against intracellular bacteria relies on immune memory. In fact, memory induction forms the basis of the success of all vaccines. Protective immunity in humans can last for more than 10 years or even lifelong, as shown for infections with or vaccinations against various viruses or bacterial toxins. Immune protection in these infections, however, also depends at least partially on memory B cells (Chapter 27). For vaccine development, it is essential to identify conditions leading to long-lasting T-cell immunity.

It is thought that during an ongoing immune response, most T cells, which receive an antigen-specific signal through the TCR together with a co-stimulatory signal, and are concomitantly propagated by cytokines, become effector T cells and eventually die of exhaustion. A small proportion that receives stimulation signals of intermediate strengths change their phenotype and become long-lived memory T cells. To become a memory T cell, anti-apoptotic molecules are produced and responsiveness to the homeostatic cytokines IL-7 and IL-15 is increased through expression of the respective cytokine receptors.⁴⁶ The current concept of T-cell memory distinguishes between two types of cells, central memory T cells (T_{CM}) and effector memory T cells (T_{EM}) on the basis of differential surface molecules and functions.⁴⁶ T_{EM} lose their lymph node homing properties (CCR7, CD62L) but rather migrate to peripheral tissues where they express effector functions, i.e., cytokine secretion and cytotoxicity. Their daily proliferation rate in humans has been estimated at 4.7% compared to 1.5% for T_{CM} . T_{CM} persist in lymph nodes and express the IL-2 receptor, which enables them to propagate quickly upon IL-2 stimulation probably from NK cells during secondary infection. T_{CM} are the source of long-term immunity in *L. major* infection. Although it is generally accepted that memory T cells can survive in the absence of antigen and MHC molecules, the situation may be different in infections with intracellular bacteria, often leading to persistent and latent infections. As of today, little is known on the induction and maintenance of long-lasting cellular immunity in infections with intracellular bacteria. Infection with *M. tuberculosis* may not cause lasting immunity, at least in susceptible individuals, as it has been reported that successfully treated patients in high transmission areas can have recurrent tuberculosis often caused by distinct strains. Similarly, protection against *L. major* is provided by short-lived effector T cells constantly stimulated by persistent parasites with regulatory T cells dampening T-effector functions (see below). Long-lived memory T cells, however, maintain immunity in the absence of parasites.⁴⁷ In experimental listeriosis of mice, induction of T-memory cells depends on the duration of infection. Further studies on this issue are required to design novel vaccination strategies in a rational way to achieve long-lasting cellular immunity against intracellular bacteria.

Regulatory T cells

Similar to most infectious agents, intracellular bacteria can cause detrimental inflammation and tissue damage due to IFN- γ -mediated Th1 responses and ultimately exacerbated pathology by TNF- α . Under

normal circumstances, control mechanisms are in place to limit immunopathology. Such countermeasures are elicited as part of the ongoing immune response during infection. The main cytokines that limit inflammation and control IFN- γ production are IL-10 and TGF- β . Although these cytokines are produced by macrophages and DC, their main producers are natural (Treg) and adaptive regulatory T cells, which are the prime cells involved in immune regulation. Natural Treg cells are responsive to IL-2 due to constitutive CD25 expression and are characterized by expression of the transcription factor FOXP3.⁴⁸ Expansion of Treg cells appears antigen-independent but they can be antigen-specific. However, Treg selectively express TLR and can be activated by LPS and possibly other TLR ligands. This makes their immediate activation during bacterial infection a most probable scenario. Although Treg cells limit CD8 T-cell responses in experimental listeriosis, their general role in infections by intracellular bacteria has not yet been fully elucidated. However, their regulatory function in other infections is better established. Gastrointestinal inflammation caused by *Helicobacter* species is limited by Treg cells. In murine leishmaniasis, Treg cells inhibit sterile elimination of the parasites by controlling Th1-cell responses but at the same time promote development of memory T cells, which protect against reinfection. Due to similar lifestyles of *Leishmania* parasites and intracellular bacteria, a comparable role in tuberculosis or leprosy can be envisaged. Antigen-dependent adaptive T cells with regulatory functions include CD8 Treg cells, CD4 T_{R1} cells, both secreting IL-10, and Th3 cells, which produce TGF- β . Recently, T_{R1} cells have been isolated from tuberculosis patients. Suppression of T-cell responses and anergy has frequently been documented for chronic infections such as tuberculosis and leprosy. Therefore, a function of Treg cells in infections with intracellular bacteria can be postulated as follows: limiting detrimental Th1-cell responses and immunopathology, prevention of total elimination of bacteria, and promotion of persistent infection and memory T cells.

B CELLS

Although B cells and antibodies appear to have a minor biological role in infections with intracellular bacteria due to their lifestyle, IgG and IgA probably play a role at the epithelial port of entry. Furthermore, facultative intracellular bacteria spend some time outside their host cells where they are accessible by antibodies. Therefore it is not surprising that antibodies are protective against *Salmonella* and *Listeria*. Finally, B cells are potent APC for soluble antigens including lipids presented by CD1c, and secrete many cytokines otherwise associated with T cells, DC, and macrophages.

ANTIGENS FOR T CELLS

Definition of the precise nature of antigens recognized by protective T cells is required for the rational design of improved vaccines and diagnostic skin test reagents. Although we understand quite well the characteristics of antigens from extracellular bacteria that are recognized by protective antibodies, virtually nothing is known about the general characteristics defining protective T-cell antigens. Three major features seem worth particular consideration.

First, it is becoming increasingly clear that bacteria capable of surviving inside host cells are a poor source of somatic antigens, and that the T-cell response against such persistent pathogens needs to focus on secreted proteins. Secreted antigens are particularly relevant to vaccine-induced

immunity, which needs to be activated as soon as possible after primary infection with the natural pathogen. Much later, when MPs are activated, intracellular bacteria will be destroyed, giving rise to somatic antigens.⁴⁹ The second major concern for rational vaccine design is the appropriate distribution of antigens between the MHC class I and II processing pathways. Soluble proteins are processed through the MHC class II pathway. Consequently, CD4 T-cell activation does not pose major obstacles to subunit vaccines. In contrast, activation of CD8 T cells depends on the efficient introduction of proteins into the MHC class I pathway (Fig. 25.5). This can be achieved either by appropriate membrane translocation systems or by promoting cross-presentation through apoptosis induction. An efficient method of achieving this is the use of recombinant bacteria. This has been demonstrated using a recombinant BCG strain expressing the listerial hemolysin protein which induces apoptosis and subsequently cross-presentation.

Third, recent studies in experimental listeriosis of mice indicate that CD8 T cells not only recognize conventional peptides, but can recognize unconventional peptides containing the *N*-formylmethionine (*N*-fMet) sequence.⁵ The *N*-fMet serves as a signal sequence for protein secretion in prokaryotes and does not exist in mammalian proteins (apart from approximately 30 proteins of mitochondrial origin). Importantly, *N*-fMet-containing peptides are recognized in the context of the MHC class Ib molecule H2-M3, which is far less polymorphic than classical MHC class I molecules. If preferential recognition of such peptides holds true for humans and for bacteria other than *Listeria*, this finding has far-reaching implications for vaccine development. It would promote the design of peptide vaccines applicable to a wide variety of individuals, independent of conventional MHC polymorphisms. In a similar way, lipid antigens presented by nonpolymorphic CD1 molecules can be envisaged as MHC-independent vaccines.

CYTOKINES

Cytokines serve as crucial signal transmitters between the cells participating in antibacterial immunity (Fig. 25.4). A characterization of cytokine mRNA levels in lesions of leprosy patients has provided important information about the cytokines operative in granulomas. The “protective” tuberculoid lesions express abundant mRNA levels of multiple cytokines, including IL-1, IL-2, IL-6, TNF, and IFN- γ , suggesting their relevance to granuloma formation and maintenance.⁵⁰ In contrast, IL-4, IL-5, and IL-10 mRNA levels are almost absent from this type of lesion, although they are highly increased in lepromatous lesions, suggesting inhibitory functions of these cytokines.

IL-12, IL-18, IFN- γ , and macrophage activation

Extensive studies on the activation of antibacterial effector functions in macrophages have revealed a central role for IFN- γ . Accordingly, IFN- γ neutralization with antibodies, or deletion of the IFN- γ gene by homologous recombination, markedly exacerbates infectious diseases such as listeriosis, tuberculosis, or typhoid in experimental animals (Fig. 25.4 and Table 25.2). IFN- γ is produced early in infection by NK cells, and later by Th1 cells. It is now clear that the production of IFN- γ by NK cells depends on prior activation by IL-12 and/or IL-18. This cytokine can be induced by components of intracellular pathogens, such as LPS, mycobacterial LAM, and lipoteichoic acid from *Listeria*. IL-12 in

concert with TNF- α induces a cytokine loop resulting in the production of IFN- γ , which in turn acts on macrophages both to activate bactericidal mechanisms and to sustain the production of IL-12 and IL-18. The importance of these cytokines in host defense against intracellular pathogens has been clearly demonstrated using gene knockout mice. These mice exhibit overwhelming susceptibility to infections with mycobacteria, *Salmonella*, and *Listeria*, which was demonstrated to occur as a direct result of the lack of macrophage activation mediated by IFN- γ . Recently these observations have been extended to humans, where patients with mutations in genes for the IFN- γ receptor or IL-12 and its receptor are highly susceptible to infections with *Salmonella*, atypical mycobacteria, and BCG.

Many nonprofessional phagocytes also respond to IFN- γ . Although in these cells the full antibacterial armamentarium operative in activated macrophages cannot be mobilized, IFN- γ stimulation causes some microbial growth inhibition. Important mechanisms represent tryptophan and iron deprivation, which are both responsible for inhibition of chlamydial growth in epithelial cells. IFN- γ also induces an array of small GTPases such as LRG-47 and IGTP. Although functional data are very limited, these cytoplasmic enzymes are putatively involved in vesicle trafficking. Mice deficient in LRG-47 are highly susceptible to *M. tuberculosis*.⁵¹ LRG-47 seems to control autophagy, a waste and recycling system functional in all eukaryotic cells.⁵² This system is enhanced in IFN- γ -activated cells and has been suggested to contribute to elimination of mycobacteria and *Listeria*.

Proinflammatory cytokines and phagocyte attraction

The recruitment of more phagocytes to the site of infection represents a vital process in the resolution of infection. This is achieved via the secretion by macrophages and endothelial cells of cytokines such as IL-1, TNF, IL-6, and chemokines. TNF and IL-1 activate the vascular endothelium to increase the expression of adhesion molecules, which promote the extravasation of lymphocytes into the infected tissue. Chemokines are a family of structurally related proteins that can be divided into three subfamilies: C-C chemokines (MIP-1 β , MCP-1, 2, 3), CXC chemokines (MIP-2, IL-8), and C chemokines (lymphotactin) (Chapter 11). These molecules are critical in controlling the migration of neutrophils (IL-8) and monocytes (MCP-1) from the bloodstream to the infected tissue.⁵³ Recently the role of chemokines in intracellular infections has been increasingly appreciated, with mice lacking the receptor for MCP-1 being deficient in their ability to clear *Listeria* infection. CCR7 binds CCL19 and CCL21 and is expressed by T cells but also by DC. Homing of DC from infected tissues to draining lymph nodes, in order to induce T cells by means of cross-presentation, depends on this chemokine receptor. It has been realized that distinct repertoires of chemokine receptors are expressed on Th1 and Th2 cells. Human Th2 cells selectively express CCR3, which is the receptor for eotaxin, RANTES, MCP-2, 3 and 4; and Th1 cells express CXCR3, which binds IFN- γ -inducible protein 10 (IP10), and monokine induced by IFN- γ (MIG), both of which are induced by IFN- γ . A similar selective expression of chemokine receptors has been noted in the murine system. The differential response to chemokines may influence the type of T cell that is recruited into a specific site during the course of disease, and thus influence the immune response elicited.

LYSIS, TISSUE DAMAGE, AND BACTERIAL KILLING

Cytolytic phenomena generally accompany infections with intracellular bacteria. Cells with cytolytic potential that are activated during such infections include PMN, blood monocytes, NK cells, and T cells.^{22, 24, 30} PMN and blood monocytes that are attracted to foci of bacterial growth nonspecifically destroy the surrounding tissue, primarily by secreting proteolytic enzymes, including elastase, collagenase, and gelatinase. These enzymes affect the integrity of both cells and extracellular matrix. They are at least partially responsible for the exudative character of early lesions. NK cells and T cells express nonspecific or specific cytolytic activity, respectively, further contributing to tissue damage. Tissue damage is generally localized to the site of microbial implantation or persistence. Cytolytic T cells probably act at advanced stages of infection and contribute to the liquefaction that follows the reactivation of dormant bacteria. Without doubt, the tissue damage caused by cytolytic mechanisms significantly determines the pathology of infectious disease. Furthermore, the release of bacteria contained within distinct foci may promote the dissemination of pathogens to distant sites. However, cytolytic mechanisms are required for protection against microbes living in protective niches, such as deactivated macrophages or nonprofessional phagocytes. Transmission of bacteria from an incapacitated cell to a highly activated professional phagocyte significantly improves bacterial elimination. Finally, cytolytic T cells may also attack intracellular microbes. Once the target cells have been lysed, bacteria can be killed by means of a specific molecule, granulysin, that is contained within the granules of the cytotoxic T cell.³¹

GRANULOMA FORMATION

The formation of a tissue granuloma is a characteristic feature of many infections caused by intracellular bacteria. The longevity of the granuloma depends directly on the continuous presence of the microbial pathogen, and the lesion generally disappears after its sterile eradication. Granulomas form the focus of the coordinated cross-talk between different types of T cells, B cells, and MP. Even if the immune system fails to eliminate bacteria completely inside the granuloma, the latter performs a protective function by containing microbes within distinct foci and preventing their dissemination. At the same time, the granuloma can be detrimental to the host because it can interfere with physiologic organ functions.

Granulomatous lesions are generally initiated by nonspecific inflammatory signals mediated by bacterial products, chemokines, TNF- α , and IL-1, which are produced by endothelial cells and MP at the site of infection (Fig. 25.6). Inflammatory phagocytes are attracted to the site of microbial replication and an infiltrative, sometimes exudative, lesion develops. Following the accumulation and activation of increasing numbers of MPs, this lesion takes a more granulomatous form. A significant number of B cells is also found, which seem to influence granuloma morphology. Once specific T and B cells have been attracted to the lesion, it transforms into a productive granuloma that provides the most appropriate tissue site for antibacterial protection. Here, activation of macrophages by IFN- γ and TNF- α causes significant microbial growth inhibition. Bacterial transmission from inefficient host cells to more potent effector cells through lysis of infected cells by cytolytic T cells further contributes to protection. At the same time, regulatory events involving IL-10 and TGF- β by Treg, T_H1, and Th3

cells are probably in place to prevent exacerbated immunopathology. Eventually, the granuloma is encapsulated by a fibrotic wall and its center becomes necrotic.⁵⁴ Both tissue reactions are primarily protective, the former by promoting bacterial containment and the latter by reducing the nutrient and oxygen supply to the pathogen.

Frequently, such a granuloma is the result of a long-lasting standoff between microbe and host defense that may last for long periods of time. As a consequence of microbial reactivation and/or weakening of the immune response, however, this tie may break down. Exaggerated macrophage activation leads to the uncontrolled expansion of necrotic lesions, affecting the physiologic functioning of the affected organ. Moreover, extensive cytolysis by MP, T lymphocytes, and newly attracted PMN and monocytes causes liquefaction of the granuloma and its rupture.⁵⁴ This event is not only responsible for extensive organ damage: it may also favor the local replication of facultative intracellular bacteria in the cellular detritus, as well as microbial dissemination to distant tissue sites and to the environment to transmit infection.

DTH REACTION

Intradermal injection of soluble proteins from an intracellular bacterium causes local infiltration of specific T lymphocytes and MP in individuals immune to the same pathogen. The reaction generally reaches its maximum between 40 and 70 hours after antigen application. This DTH reaction has been used successfully for the diagnosis of infections with various intracellular bacteria, particularly *M. tuberculosis*/*M. bovis* and *M. leprae*, because of the difficulty in isolating such microbes from internal organs, where they persist without causing clinical disease: It should be emphasized that a positive DTH response directly reflects the existence of a specific T-cell response and only indirectly indicates microbial existence in the host, and is by far no conclusive indication of a protective immune status. The DTH response is mediated by CD4 $\alpha\beta$ T cells, with recent evidence suggesting a vital role for TNF- α in the induction of chemokines. Because soluble antigens are processed inefficiently, if at all, through the MHC class I pathway, CD8 T cells, which are important elements of protective immunity, are not challenged by DTH antigens. Thus, the DTH response reflects an important arm, but not the full armamentarium, of protective immunity against intracellular bacteria. As a further complication, the DTH antigen mixture may miss antigens relevant to protection. According to the stage of disease, different ratios of secreted versus somatic antigens may be required. Where secreted antigens may be particularly important during persistent infection, somatic antigens may become more important once bacteria are efficiently destroyed by activated macrophages.

Although DTH responses are generally positive in immune but non-diseased individuals, they are frequently absent during full-blown disease, such as miliary tuberculosis and lepromatous leprosy. The reasons for this anergy are incompletely understood but appear to involve immunosuppression, the absence of appropriate antigens in the DTH reagent, the accumulation of specific T cells at the site of disease manifestation, and their concomitant absence from the periphery.

LOCAL IMMUNITY AT THE PORT OF ENTRY

Intracellular bacteria enter the host through two major ports. Pathogenic *Rickettsia* and *Ehrlichia* species and often *Coxiella burnetii* are introduced directly into the vascular bed by arthropod bites or through abraded skin;

A Bacterial phagocytosis by macrophages

B Granuloma formation at site of bacterial replication

C Bacterial containment in granuloma

D Granuloma liquification, rupture and bacterial dissemination

Fig. 25.6 Cells involved in granuloma formation and rupture. This figure uses tuberculosis to illustrate the major events in granuloma formation. **(A)** Bacteria that have entered the alveolus are engulfed by alveolar macrophages, which translocate bacteria into the lung interstitium. **(B)** Inflammation develops, which causes extravasation of blood monocytes. Proinflammatory cytokines and chemokines are produced by macrophages and endothelial cells surrounding this focus. **(C)** Specific T cells are attracted to the site of microbial deposition and granuloma formation is initiated. The protective granuloma is maintained by the influence of the various T-cell subsets and cytokines. The center becomes necrotic and a fibrous wall encloses the lesion, promoting microbial containment. **(D)** Cytolytic mechanisms cause microbial release from deactivated macrophages and their inhibition by more efficacious effector cells. A preponderance of cytolytic mechanisms causes rupture of the granuloma. As a consequence, exaggerated tissue destruction and microbial dissemination occur.

all the other intracellular bacteria invade the host through mucosal tissues. *Mycobacterium tuberculosis*/*M. bovis*, *L. pneumophila*, *C. burnetii*, *Chlamydia psittaci*, *C. pneumoniae*, and *Brucella* sp. preferentially intrude the lung; *S. typhi*/*S. paratyphi*, *L. monocytogenes* and sometimes *M. bovis*, *M. avium*, and *Brucella* sp. gain entrance through the gut; *C. trachomatis* invades the urogenital tract and eventually the ocular system; and *M. leprae* penetrates the oropharynx. The local immune response in the mucosa therefore represents an important barrier to infection (Chapter 19). The immune armamentarium at this strategically important point includes specific IgA and IgG antibodies, the intraepithelial lymphocytes, the lamina propria lymphocytes, and the cells in the local lymphoid follicles. Frequently, the immune response initiated in these follicles is directed toward the Th2 cell arm. The relatively high proportion of $\gamma\delta$ and NKT cells among intraepithelial lymphocytes, as well as their broad antigen specificity, suggests a particular role for these cells in early immune surveillance against intruding pathogens. Many foodborne pathogens initiate infection by adherence to the microfold (M) cells distributed among intestinal epithelial cells.⁵⁵ Because these cells are specialized for the uptake of nutrients from the intestine, microbial adhesion induces transcytosis, which opens passage to the Peyer's patches beneath. Bacterial invasins are central to this step. In the Peyer's patches,

MP and DC engulf microbial invaders but fail to eradicate the majority of them. As a corollary, these cells serve as a local niche and/or transit system to deeper tissue sites. To achieve successful entrance through the lung, microbes must be inhaled within minute droplets that reach the alveolar compartment. There, alveolar macrophages and DC engulf the bacteria, yet these MP again fail to kill intracellular bacteria, and serve as a transport system to the lung interstitium as well as to the draining lymph nodes.

GENETICS OF HOST RESISTANCE TO INTRACELLULAR BACTERIA

It has been appreciated for many years that the genetic makeup of the host can influence both resistance to and the outcome of infection. Over 20 years ago, studies in the murine system revealed that a genetic factor controlled resistance to the antigenically unrelated intracellular pathogens *S. typhimurium*, *Leishmania major*, and *M. bovis* BCG. Subsequently this gene has been identified and termed *Nramp1* for natural resistance-associated macrophage protein. This gene encodes for a protein of

phagocytic cells and a single-point mutation at amino acid 169 (glycine for aspartic acid) converts mice from a resistant to a susceptible phenotype. Functional studies using congenic mouse strains have demonstrated that *Nramp 1* plays a critical role in early macrophage activation events via pleiotropic effects such as the regulation of iNOS, TNF- α , the chemokine KC, and MHC class II expression, and ultimately biases towards Th1-cell development.⁵⁶ *Nramp1* is most probably a transporter for divalent metal ions such as iron or manganese on late endosomal membranes. Despite the conflicting evidence for the role of *Nramp1* in resistance of mice to *M. tuberculosis*, a large case-control study in Africans strongly associated an *NRAMP1* polymorphism with tuberculosis.⁵⁷ Polymorphisms of the genes for IFN- γ receptor, vitamin D receptor, and TLR-2 have also recently been associated with enhanced susceptibility to tuberculosis.^{58–61} The latter two polymorphisms may influence production of the bactericidal peptide cathelicidin.³¹ TLR-2 polymorphisms have also been associated with disease outcome in leprosy.⁵⁹ Analysis within a region of chemokine genes revealed a functional promoter polymorphism (*GG* versus *AG*) in the gene for MCP-1, a chemoattractant for monocytes and T cells, associated with increased susceptibility to pulmonary tuberculosis. Carriers of the *GG* genotype produce more MCP-1 but less IL-12, which is taken as the basis for higher susceptibility to tuberculosis of these carriers.⁶²

KEY CONCEPTS

HOST EFFECTOR MECHANISMS OPERATIVE IN GRANULOMAS

- >> Macrophage activation by interferon- γ , tumor necrosis factor (TNF), and other cytokines
Microbial growth inhibition (protective)
- >> Lysis of incapacitated macrophages by cytolytic T cells
Microbial release facilitating uptake by more efficient effector cells and direct killing of the bacteria (protective), or
Microbial dissemination (pathogenic)
- >> Central necrosis mediated by TNF
Microbial growth inhibition (protective)
- >> Fibrotic encapsulation by TNF
Microbial containment (protective)
- >> Exaggerated necrosis and fibrosis
Tissue damage (pathogenic)
- >> Central liquefaction by cytolytic T cells, activated macrophages, polymorphonuclear leukocytes (PMN)
Tissue damage and promotion of microbial growth (pathogenic)
- >> Rupture of granuloma by cytolytic T cells, activated macrophages, PMN
Tissue damage and microbial dissemination (pathogenic)
- >> Counter-regulation by regulatory T cells via interleukin-10 and transforming growth factor- β
Minimizing inflammation and tissue damage (protective)
Impairing protective immune response (pathogenic)

The influence of genes of the MHC has also been examined in relation to infections caused by intracellular bacteria. Human leukocyte antigen (HLA) segregation has been described in *C. trachomatis* infections where HLA-DR53 correlated with resistance and HLA-DR16 associated with blindness. Additionally, in a large trial in Venezuela, HLA-DR genotypes were associated with responses to the mycobacterial purified protein derivative (PPD). Positive cell-mediated immune responses to PPD were associated with DR3 and DR4 and negatively associated with DR2 and DR5. The converse was observed for antibody responses, suggesting that HLA-DR alleles differentially direct Th1 and Th2 responses. In terms of HLA association in clinical mycobacterial diseases, family studies have proved an allelic association in leprosy, but the results for tuberculosis have been more conflicting, both clinically and experimentally.⁶³

CONCLUSION

It is being increasingly recognized that the interaction between intracellular bacteria and the immune system is not of the 'all or nothing' type but is instead a 'continuous struggle.' This realization has far-reaching implications for preventive and therapeutic strategies against intracellular bacterial infections. First, vaccination against intracellular bacteria has not yet been effected satisfactorily because of the involvement of several distinct T-cell subsets with different modes of stimulation and activity profiles. Second, chemotherapy has frequently proved suboptimal for the sterile eradication of bacteria hidden in cellular niches. A better understanding of the complex cross-talk between cytokines, T lymphocytes, macrophages, and infected host cells will no doubt directly promote the development of improved control measures. It is interesting in conclusion to recall that the discovery of several fundamental principles of immunology was stimulated by early attempts to treat and prevent infections with intracellular bacteria. These include the characterization of macrophages and their contribution to antibacterial defense by Elias Metchnikoff, and the description of granulomatous lesions and DTH responses in tuberculosis by Robert Koch.

KEY CONCEPTS

WHAT IS REQUIRED FROM A VACCINE AGAINST INTRACELLULAR BACTERIA?

- >> Activation of innate immunity (Toll-like receptor, natural killer cells)
- >> Induction of interleukin-12 (IL-12) and IL-18
- >> Activation of a broad array of T-cell populations
- >> Promoting interferon- γ -secreting and cytotoxic T cells
- >> Inhibition of regulatory T cells and induction of long-lasting T-cell memory
- >> Ideal goal: induction of sterile pathogen eradication
- >> Second-best goal: sustaining latent infection and prevention of disease reactivation

Immune responses to spirochetes

26

Juan Anguita, Chris M. Olson Jr, Erol Fikrig

■ CHARACTERISTICS OF SPIROCHETES ■

GENERAL FEATURES

Spirochetes constitute a unique and diverse group of bacteria that inhabit many different environments such as soil, deep marine sediments, arthropods, and mammals. Spirochetes are the causative agents of numerous human illnesses, including syphilis and Lyme disease.

Spirochetes are characterized by a typical spiral shape with a distinctive flat-wave morphology. Cellular dimensions vary over a wide range among spirochetes, with a diameter of 0.09–0.75 μM , and lengths that range from 3 to 500 μm . They are motile organisms with a multilayered outer membrane that encapsulates a peptidoglycan layer surrounding their inner membrane. Motility is due to the presence of endoflagella located in the periplasmic space. These axial filaments are arranged in a bipolar fashion and extend toward the opposite end of the cell (Fig. 26.1). The viability of the organism is dependent on an intact outer membrane, which can be damaged by variations in osmolarity, antibodies, or complement, resulting in the loss of intracellular components and ultimately death of the bacterium.

Several spirochetal species are able to induce disease in mammals (Table 26.1). Lyme disease was first discovered in 1975 as an illness affecting a cluster of children in Lyme, Connecticut. In 1981 the agent of Lyme disease was identified as *Borrelia burgdorferi*.¹ In contrast, *Treponema pallidum* subspecies *pallidum* is the causative agent of venereal syphilis, a disease that has been recognized for over 500 years, although its agent was not determined until 1905.²

The genomes of *B. burgdorferi* and *T. pallidum* have recently been sequenced.^{3,4} Despite similar ancestry and morphological features, these spirochetes have striking differences at the genetic level that may account for the differences in their lifecycles, environmental adaptations, and the diseases caused by them. Both *B. burgdorferi* and *T. pallidum* have relatively small genomes, when compared to other microorganisms. *B. burgdorferi*, however, has one of the most complex genomes known

among prokaryotes. This spirochete has a single linear chromosome and 21 plasmids, the largest number of plasmids of any characterized prokaryote. Of the 21 plasmids, nine are circular and 12 are linear. Furthermore, less than 10% of *B. burgdorferi* plasmid coding regions are found in other microorganisms, including spirochetes, which underscores the uniqueness of this spirochete amongst all bacterial microorganisms. Unlike *B. burgdorferi*, *T. pallidum* contains a single circular chromosome with no plasmids. Yet, 476 open reading frames (ORFs) in *T. pallidum* have orthologous genes in *B. burgdorferi*. Almost 60 of these orthologous genes encode proteins of unknown biological functions that are specific to spirochetes, which may be involved in the pathology associated with infection.

Typically, Gram-negative microorganisms have lipopolysaccharide (LPS)-encoding genes; however, *B. burgdorferi* and *T. pallidum* do not. Lipoproteins are the major immunogens of *B. burgdorferi* and most likely *T. pallidum*, and thus they are the dominant proinflammatory agonists of spirochetal infection. Some 5% of the chromosomal ORFs of *B. burgdorferi* encode putative lipoproteins, whereas 14.5–17% of the functionally complete ORFs contained in these plasmids encode lipoproteins. Interestingly, only 2.1% of the *T. pallidum* ORFs encode putative lipoproteins. The abundant lipoprotein-coding potential of *B. burgdorferi* suggests that lipoproteins may be important for the survival of the spirochete. In fact, as a result of increased temperature and nutrient availability, as well as reduced pH, expression of several *B. burgdorferi* lipoproteins is augmented upon tick feeding and transmission into the mammalian host.⁵ For instance, the lipoprotein outer-surface protein (Osp) A is expressed at high levels in the gut of the unfed tick, but upon feeding OspA expression is downregulated, and the expression of OspC increases 90-fold.⁵ It is thought that many Osps have adhesive functions, and it has been shown that OspA is involved in the attachment of *B. burgdorferi* to the gut of the tick through an interaction with the tick receptor TROSPA.⁶ Furthermore, OspC may be necessary for the migration of *B. burgdorferi* from the gut of the tick to the salivary glands, where it is transmitted into the mammalian host during tick engorgement, and also for survival in the mammalian host.

Fig. 26.1 (A) *Borrelia burgdorferi* structure is characterized by a distinctive flat-wave morphology consisting of approximately 18 bends and a length of 20–30 μm . (B) A cross-section of this spirochete reveals the endoflagella, which are responsible for the unique morphology and motility of this organism.

CLINICAL RELEVANCE

- >> Pathology arising from infection with *Borrelia burgdorferi* and *Treponema pallidum* in untreated individuals includes:
- >> Early localized disease
- >> Early disseminated disease
- >> Persistent infection

PATHOLOGY ARISING FROM INFECTION WITH *B. BURGDORFERI* OR *T. PALLIDUM*

LYME DISEASE

B. burgdorferi sensu stricto (*B. burgdorferi*) is the etiologic agent of Lyme disease in the USA and other parts of the world, while *B. afzelii* and *B. garinii* are agents of Lyme disease that are restricted to Europe and Asia.¹ Infection with Lyme disease-causing spirochetes has also been observed in Japan, Russia, and China. In the USA, transmission of the spirochete is by hard-bodied ticks of the *Ixodes* complex, mainly *I. scapularis* and *I. pacificus*. According to the Centers for Disease Control, Lyme disease is the most common tickborne disease in the USA.⁷

An early hallmark of infection is the appearance of a skin rash known as erythema migrans (Fig. 26.2), which often appears during the first week of infection (stage I, Lyme disease). Other symptoms occurring at this time may include fever, headache, malaise, myalgia, and/or arthralgia. The spirochete then disseminates (stage II, Lyme disease) and

symptoms can include conduction system abnormalities, meningitis, and acute arthritis, which appear in 60% of untreated individuals in the USA. Some untreated individuals develop stage III Lyme disease, which is generally characterized by prolonged infection with the spirochete. Late-stage symptoms may include chronic arthritis, neuroborreliosis, or cutaneous lesions such as *acrodermatitis chronica atrophicans*.

Diagnosis

A detailed clinical history and comprehensive physical examination are critical for the accurate diagnosis of Lyme disease. Appropriate laboratory testing, however, can be a valuable diagnostic aid.

In the USA, more than 70 Food and Drug Administration (FDA)-approved serologic assays for the diagnosis of Lyme disease exist. In 1995 the Association of Public Health Laboratories and the Centers for Disease Control implemented a two-tiered approach for the serodiagnosis of Lyme disease in the USA, and this remains the gold standard today. Using this approach, serum is first tested for the presence of *B. burgdorferi*-specific antibodies by a sensitive method, such as enzyme-linked immunosorbent assay (ELISA) or an immunofluorescent assay (IFA) – an ELISA is most commonly used. Serum testing negative for antibodies generally need not be tested further; however, those found to be positive or equivocal are further evaluated by the more specific immunoblotting for immunoglobulin M (IgM) and IgG antibodies. The detection of at least two of three specific bands in IgM or five of 10 specific bands in IgG is considered positive. It should be noted that patients with early Lyme disease often report to a physician during the first few days of infection, at which time a detectable humoral response may not have developed. If these individuals are rapidly and effectively treated, then significant *B. burgdorferi*-specific antibody responses may not develop. Consequently, the two-tiered approach is considered highly sensitive during the later stages of Lyme disease (> 90%) and less sensitive during very early infection. It should be noted that a positive serologic test, particularly IgG, is evidence of exposure to *B. burgdorferi*, but does not necessarily indicate active infection. All serologic tests must be evaluated in conjunction with the clinical assessment of the attending physician.

Culture and polymerase chain reaction (PCR) detection of *B. burgdorferi* may be very useful to detect active infection, particularly of the skin, joints, and central nervous system. Culture, however, is generally limited to research labs, and the sensitivity and specificity of PCR can vary greatly among testing centers.

Treatment

During early stages of Lyme disease, such as that during which erythema migrans is present, oral administration of doxycycline (100 mg twice daily) or amoxicillin (500 mg 3 times a day) for approximately 2 weeks is recommended.⁸ Doxycycline has the advantage of being effective against *Anaplasma phagocytophilum*, which may also be transmitted by ticks. In areas where *B. burgdorferi* infection is prevalent, some experts recommend antibiotic therapy for individuals who served as hosts to *I. scapularis* ticks that were attached longer than 48 hours – the time required for transmission of the spirochete. It is extremely difficult, however, to make consistently accurate determinations of the species of tick and the degree of engorgement. Furthermore, randomized double-blind clinical trials involving individuals who were bitten by *I. scapularis* ticks led to the conclusion that treating all individuals who remove vector ticks with antibiotics is probably not warranted.⁸

Table 26.1 Spirochetes are the causative agents of many diseases, which can have social as well as lasting health-related consequences

<i>Major diseases caused by spirochetal infection</i>				
Disease	Agents	Distribution	Transmission	Symptoms
Lyme disease	<i>Borrelia burgdorferi</i> <i>B. garinii</i> <i>B. afzelii</i> <i>B. andersoni</i> <i>B. japonica</i> <i>B. lusitaniae</i> <i>B. valaisiana</i>	North America, Europe Asia, Europe Asia, Europe North America Japan Southern Europe Europe, Ireland, UK	Tick engorgement	Development of a skin rash known as <i>erythema migrans</i> , accompanied by other symptoms such as malaise, myalgia, and/or arthralgia. Symptoms can progress to include carditis and arthritis. Persistent infection can result in chronic arthritis, neuroborreliosis, or cutaneous symptoms (acrodermatitis chronica atrophicans)
Relapsing fever	<i>B. hermsii</i> <i>B. turicatae</i> <i>B. parkeri</i> <i>B. mazzotti</i> <i>B. venezuelensis</i> <i>B. duttoni</i> <i>B. crocidurae</i> <i>B. persica</i> <i>B. hispanica</i> <i>B. latyschewii</i> <i>B. caucasica</i>	Western USA Southwestern USA, Mexico Western USA Central America Central America Sub-Saharan Africa North Africa, Middle East Middle East, Central Asia Iberian peninsula, North Africa Iran, Iraq, Eastern Europe Iraq, Eastern Europe	Tick engorgement	Clinical manifestations of infection include high-density spirochetemia, high fever, myalgias, and arthralgias, and can even include cerebral hemorrhage and fatality
Venereal syphilis	<i>Treponema pallidum pallidum</i>	Worldwide	Sexual contact	Disease progresses from a primary lesion (chancere) to a secondary eruption and then a latent period, and if left untreated tertiary symptoms may appear
Endemic syphilis or Bejel syphilis	<i>T. pallidum endemicum</i>	Eastern Mediterranean region, West Africa	Nonsexual skin contact	Symptoms begin with a slimy patch on the inside of the mouth followed by blisters on the trunk and limbs. Bone infection in the legs soon develops, and, in the later stages, lumps may appear in the nose and on the soft palate of the mouth
Yaws	<i>T. pertenue</i>	Humid equatorial countries	Nonsexual skin contact	Destructive lesions of the skin and bones, which is rarely fatal but can be debilitating

Continued

Table 26.1 Spirochetes are the causative agents of many diseases, which can have social as well as lasting health-related consequences—Cont'd

Major diseases caused by spirochetal infection				
Disease	Agents	Distribution	Transmission	Symptoms
Pinta	<i>T. carateum</i>	Mexico, Central America, South America	Nonsexual skin contact	Dark skin lesions found on those areas of the body that are exposed to sunlight. Eventually, the skin lesions become discolored
Leptospirosis	<i>L. interrogans</i>	Worldwide	Urine from an infected animal	Symptoms include fever, headache, chills, nausea, and vomiting, eye inflammation, and muscle aches. In more severe cases, the illness can result in liver damage and kidney failure

VENEREAL SYPHILIS

Infection with the agent of syphilis, *T. pallidum* subspecies *pallidum*, occurs worldwide. *T. pallidum* is an obligate human parasite that is almost exclusively transmitted when contact with infectious exudates from lesions of the skin and mucous membranes of infected individuals occurs.

Clinically, this treponemal infection is first characterized by the formation of a hardened and painless ulcer at the initial site of infection. This primary lesion, called a chancre, forms after invasion of the

bloodstream by the spirochete. Four to 6 weeks following infection, the edges of the chancre roll inwards and upwards and, in most cases, a secondary eruption appears, often accompanied by a rash on the palms of the hands and the soles of the feet. The secondary manifestations spontaneously resolve within weeks to a year. Long periods of latency, and late lesions of the skin, bone, viscera, cardiovascular and central nervous systems, can follow.

Diagnosis

Much like Lyme disease, the diagnosis for syphilis is based on the clinical presentations of the disease and serologic tests. In addition, dark-field microscopy may be used for the identification of *T. pallidum* in the serous exudates of the chancre. This approach, however, is limited by the number of live treponemes in the exudates and by the presence of nonpathologic treponemes in oral and anal lesions; as such, negative examinations on three independent days are required before a lesion is considered negative for *T. pallidum*.

Infection with *T. pallidum* leads to the production of nonspecific antibodies, which is the basis for other diagnostic tests, such as the traditional nontreponemal serologic tests, including the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests. Because these tests are nonspecific, false-positive reactions may occur as a result of pregnancy, autoimmune disorders, or infections. Therefore, treponemal-specific tests, which detect antibodies to various antigens of *T. pallidum*, are often used to confirm the results of a non-specific test. Interestingly, treponemal-specific tests are just as sensitive as nontreponemal tests; however, they are much more difficult and expensive to perform, which limits their use. These tests include, but are not limited to, the enzyme immunoassay test for *T. pallidum*-specific IgG (EIA), *T. pallidum* hemagglutination test (TPHA), fluorescent treponemal antibody-absorption test (FTA-abs), and ELISA.

CLINICAL PEARLS

- >> The development of pathology following infection with *Borrelia burgdorferi* is a dynamic process affected by many variables, including:
- >> The number of spirochetes in the affected organs
- >> Spirochetal virulence factors
- >> The host immune response generated against the *B. burgdorferi*

Treatment

Susceptibility to infection with *T. pallidum* is universal, although only 30% of exposures with lesions teeming with the spirochete result in infection. Infection results in gradual development of immunity against *T. pallidum* and often against heterologous treponemes as well. However, treatment with long-acting penicillin subverts the development of immunity against *T. pallidum*. A single intramuscular dose of 2.4 million units the day that the primary, secondary, or latent syphilis is diagnosed is effective at killing the spirochetes. For people who are allergic to penicillin, there are alternative treatments such as doxycycline.

IMMUNE RESPONSES TO B. BURGDORFERI

The Lyme disease spirochete has been the subject of intensive investigation in order to elucidate the mechanisms that contribute to its ability to cause persistent infection and multisystemic disease, despite the development of strong immune responses. The control of the number of bacteria in the mammalian host is likely to depend on several immune effector mechanisms, such as the development of antibody responses and the capacity of phagocytic cells to clear spirochetes.

INNATE IMMUNITY

The initial encounter of a pathogen with cells of the host initiates a cascade of responses that lead to the upregulation of chemokines and cytokines, adhesion molecules, and a vast array of other effector molecules (Chapter 3). These events are aimed at the recruitment of phagocytic cells, their activation, and the eventual development of the adaptive immune response. The initial recognition of pathogens by cells of the innate immune system and others, like endothelial and epithelial cells, depends on the rapid detection of the microorganism. This depends on the presence of germline-encoded pattern recognition receptors (PRRs) that distinguish infectious agents from host factors. These pattern recognition molecules are being extensively studied because they not only mediate these initial responses to microorganisms, but also modulate the extent and quality of acquired immune responses. Toll-like receptors (TLRs), identified as the mammalian counterparts of the Toll protein in *Drosophila* that mediate immune responses to fungi, are the most studied, but do not constitute the only mechanism by which innate immune cells recognize infecting microorganisms. Each PRR recognizes a specific structure that is present in a group or groups of microorganisms and that distinguishes them from the more specific recognition of spirochetal

antigens by the T- and B-cell receptors. Thus, TLR4 recognizes LPS, which is present in Gram-negative bacteria. The recognition of patterns instead of specific antigens provides the innate immune system with a rapid way to respond to infecting organisms until the more specific response mediated by T and B cells develops.

B. burgdorferi does not contain LPS, in contrast with other members of the spirochete group, and therefore does not engage TLR4. The most important pattern recognized by innate immune receptors is constituted by the surface lipoproteins of the spirochete and this seems to be true for whole spirochetes and lysates. It is not clear what the specific interaction between whole spirochetes and antigens exposed by bacterial lysis with immune cells is *in vivo*. However, it is conceivable that both elicit immune responses, since *B. burgdorferi* is likely to die *in vivo*, for example in the presence of antibody in a process that does not require complement or phagocytosis.

The interaction of *B. burgdorferi* lipoproteins with complexes formed by TLRs 1 and 2 on the surface of innate immune and other cell types initiates a series of signaling cascades that results in the production of proinflammatory cytokines (interleukin (IL)-1 β , tumor necrosis factor (TNF)- α , IL-12, and IL-18, among others), chemokines (IL-8, MCP-1, KC), metalloproteinases and adhesion molecules (E-selectin, VCAM-1, and ICAM-1).⁹ These proteins mediate both the inflammatory response to the spirochete through the production of proinflammatory cytokines and chemotactic factors that further induce the recruitment of inflammatory cells. These products also modulate adaptive immune responses, through increased antigen presentation, induction of co-stimulatory signals on antigen-presenting cells and the production of cytokines that influence CD4 T-cell differentiation and effector function (Fig. 26.3).

Phagocytic cell responses to the spirochete mediate a major previously unrecognized role in the control of bacterial numbers, presumably by their capacity to engulf the bacteria. Even though phagocytic cells are able to engulf bacteria in the absence of antibody through a potential interaction with the mannose receptor,¹⁰ experiments in TLR1- or TLR2-deficient mice have shown significant increases in their bacterial burden, underscoring the importance of TLR-mediated activation of phagocytic cells. These observations emphasize the necessity to maintain an active phagocytic cell compartment in spite of the inflammatory response that it generates in response to infection.

This conclusion has been further confirmed with the infection of mice that are deficient in MyD88, an early signaling component that mediates TLR-induced signals. It is clear that TLR signaling is involved in many of the early innate immune responses to *B. burgdorferi*; however, the engagement of TLR 2/1 complexes by spirochetal lipoproteins has a role in the manifestation of pathology associated with *B. burgdorferi* infection, which exposes a puzzling dichotomy. What is the role of this interaction in the manifestation of disease versus its role in resolution of spirochetal infection? This question remains to be answered, especially because of contradicting reports of arthritis development upon infection of TLR1-, TLR2-, or MyD88-deficient mice. The development of arthritis in the absence of TLRs, CD14, or MyD88 suggests that alternative pathways exist that trigger the inflammatory response to the spirochete. It is conceivable that the interaction of *B. burgdorferi* with resident cells of the invaded tissues through the specific interaction of bacterial proteins (Bbk32, DbpA and B, P66) with host factors (fibronectin, decorin, integrins) allows their homing and the initiation of signals for the production of chemokines that attract infiltrating phagocytic cells. These basally activated infiltrating cells may still be able to induce

Fig. 26.3 The interaction of *Borrelia burgdorferi* with Toll-like receptor (TLR) 1/2 complexes on the surface of innate immune and endothelial cells mediates the inflammatory response to the spirochete. TLR-driven proinflammatory cytokine production as well as antigen presentation by professional antigen-presenting cells (APCs) leads to the activation of CD4 effector T cells, which is marked by the production of interferon- γ . Likewise, TLR- and tumor necrosis factor- α receptor signaling lead to the upregulation of chemokines by endothelial cells. Overall, these responses lead to increased activation and recruitment of innate immune cells in sites of infection.

low levels of inflammation that nevertheless may be compensated with the increased insult resulting from the higher number of bacteria, independent of their interaction with the spirochete with TLRs that signal through MyD88. The inability of these phagocytic cells to eliminate *B. burgdorferi* effectively even in the presence of a strong antibody response leads to increased bacterial burdens and an overall inflammatory response that is equivalent to or superior than the one produced in the presence of functional TLRs. In any case, these results highlight the complexity of the innate immune response to the spirochete. It is likely that the early control of infection through innate immune defenses is important for controlling bacterial burden until the more powerful and specific adaptive immune response can completely resolve the infection.

Phagocytic cell recruitment

The recruitment of phagocytic cells into sites of infection is mediated by the production of chemokines, increased vascular permeability, and upregulated expression of cell adhesion molecules in endothelial cells. *B. burgdorferi* induces the upregulation of these factors in different cell types. Chemokine production at sites of pathology in disease-susceptible C3H/HeJ mice and -resistant C57BL/6 mice show that

inflammation is related to increased production of neutrophil and monocyte-macrophage chemokines, KC and MCP-1, respectively.¹¹ In patients, the production of chemokines, especially IL-8, during the initial response to *B. burgdorferi* correlates well with the onset of symptoms known to occur during the early stages of infection, suggesting that their production is increased during the beginning of the infection to recruit phagocytic cells, which are involved in the initial clearance of the spirochete. Overall, these results also suggest that the chemokine response is modulated once the infection progresses, and that progression of the disease may be dependent on the regulation of these chemoattractants whose production might be altered by the presence of the infiltrating cells.

Complement

The complement system is a key component of the innate immune system (Chapters 3 and 20). It comprises a collection of serum proteins and cell surface receptors that are involved in the early response to pathogens, including *B. burgdorferi*.¹² Destruction of microorganisms via complement involves the formation of a pore in the microbial cell membrane by the membrane attack complex (MAC), which results in the lysis of the organism. Three different pathways elicit complement activation: the classical (antigen antibody-mediated), lectin, and alternative (pathogen surface) pathway. These pathways converge at the level of C3 convertase, a protease that cleaves complement component C3 into C3a and C3b. As a result, C3b can either bind to the surface of the bacteria and facilitate internalization of the spirochete via opsonization or bind C3 convertase and facilitate the deposition of downstream components on to the surface of the spirochete resulting in the formation of MAC and lysis of the cell.

B. burgdorferi activates the classical and alternative pathways of the complement cascade.¹³ Moreover, the activation of complement has been associated with dramatic decreases in spirochetal numbers in different tissues of infected mice, indicating the importance of the complement system early in *B. burgdorferi* infection. However, complement-independent, antibody-mediated killing of spirochetes has been extensively reported, although the relative contribution of both mechanisms is not completely clear *in vivo*.

The members of the *B. burgdorferi sensu lato* group, which includes *B. burgdorferi sensu stricto*, *B. garinii*, and *B. afzelii*, have evolved a variety of mechanisms enabling them to escape complement-mediated lysis, including the expression of complement regulator-acquiring surface proteins (CRASPs). Of these CRASPs, the ERP (OspEF-related protein) family of outer-membrane proteins serves as binding sites for the complement inhibitor factor H and factor H-like protein 1 (FHL-1).⁹ The interaction of factor H with these proteins recruits a protease (factor I) that cleaves and inactivates the complement serum proteins C3b and C4b. Cleavage of these two complement proteins prevents the deposition of downstream components on to the surface of the spirochete, thereby halting the formation of the MAC. *B. burgdorferi* also express a CD59-like molecule on the outer membrane, which can inactivate MAC and prevent complement-mediated lysis.¹⁴ It has been speculated that most *Borrelia* are able to evade complement-mediated lysis, and recently a novel protein expressed by *B. hermsii* (a relapsing-fever spirochete) has been discovered that affords protection to spirochete by inactivating C3b.¹⁵ Because of the ability for many infectious strains to avoid complement-mediated lysis, the activation of complement is not required for the resolution of many infections with *Borrelia* species.

KEY CONCEPTS

PROTECTIVE VERSUS PATHOLOGICAL RESPONSES TO *BORRELIA BURGDORFERI*

- >> The early immune response to *B. burgdorferi* is necessary to control spirochetal burden; however, alone it is not sufficient to resolve infection
- >> The T-cell-mediated response appears to be involved in pathology arising from infection
- >> The T-cell-independent B-cell responses are critical for resolving infection with *B. burgdorferi*

ADAPTIVE IMMUNE RESPONSES

It is well established that after presentation of antigen by macrophages, dendritic cells, or B cells, to naïve CD4 T cells, these naïve cells differentiate into either Th1 or Th2 effector T cells (Chapter 17). Through their production of interferon- γ and TNF- β , Th1 cells are regulators of the cell-mediated inflammatory reaction, which is characterized by macrophage activation, stimulation of CD8 T cells, and production of opsonizing IgG antibodies. Th2 cells produce IL-4, IL-5, IL-6, IL-10 and IL-13 and regulate the antibody response to pathogens by controlling the differentiating B cells and promoting Ig class switching. Generally, infections with intracellular pathogens induce a Th1 response that is protective, while extracellular pathogens induce an antibody-mediated Th2 response. The most powerful inducer of differentiation of naïve CD4 T cells into Th1 or Th2 effector cells is the local cytokine environment. IL-12 directs the differentiation of naïve effector T cells towards the Th1 phenotype, while IL-6 (through an IL-4-dependent mechanism) and IL-4 drive differentiation towards the Th2 phenotype. Interaction of *B. burgdorferi* antigen with TLRs drives the production of IL-12 and the differentiation of naïve CD4 T cells into Th1 effector cells. Thus, TLRs are important to bridge the innate and adaptive immune responses.

The development of an imbalanced immune response can have pathological consequences. Therefore, it has been speculated that the pathology following infection with *B. burgdorferi* is often the result of a shift in the immune response towards the Th1 phenotype, resulting in more inflammation and less antibody production. In fact, it has been shown that Th1 cells dominate the immune response in the synovial fluid of patients with Lyme disease, and that the severity of arthritis correlates directly with the ratio of Th1 to Th2 cells in the synovium, such that the higher the ratio the more severe the inflammation, indicating that Th1 cells are directly involved in the pathogenesis associated with Lyme disease.¹⁶

The role of T-cell-mediated immunity during infection with *B. burgdorferi* and other members of the *Borrelia* genus appears to contribute to pathology associated with infection, while the resolution of spirochetal infection with *B. burgdorferi* does not require functional T cells. Furthermore, nude mice and T-cell-depleted mice resolve *B. turicatae* infection, thereby preventing the onset of symptomatology associated with relapsing fever.¹⁷ However, carditis, which is a *B. burgdorferi*-induced inflammatory phenomenon with a higher incidence in the murine model of Lyme borreliosis than human disease, seems to require a Th1 response for resolution.

The specific contribution of Th1 effector cells in the progression of disease mediated by infection with *B. burgdorferi* is not yet known. It has been hypothesized, however, that Th1 responses sustained by presentation of autoantigens is involved in the development of an unusual form of antibiotic-resistant chronic Lyme arthritis.¹⁸ Certain individuals possessing specific alleles of class II major histocompatibility complex (MHC) molecules (HLA-DR4) are purportedly genetically predisposed to developing treatment-resistant Lyme arthritis. One of these alleles, identified as DRB1-0401, may bind to a molecular mimic of OspA (hLFA-1), and the presentation of this molecule to OspA-reactive, Th1 effector cells in the proper context is postulated to lead to activation of T cells, long after *B. burgdorferi* infection has been resolved.¹⁹

Interferon- γ , which is produced by these Th1 effector cells, has been shown to be dispensable for the genesis of acute murine arthritis. These results arose from the infection of mice that lack either the cytokine or the alpha subunit of its receptor. However, the modulation of the Th1 response by alteration of the cytokines that mediate their differentiation, such as IL-12 and IL-6, suggest the opposite. Interferon- γ has also been shown to help the persistence of the spirochete in the murine host by inducing an increased rearrangement at the Vls locus.²⁰ It should be noted that the route of infection greatly affects the inflammatory response in both the joints and the heart of mice infected with the spirochete, and may partially account for differences in experimental results. Infection by syringe in the footpad of mice results in increased arthritis while carditis is reduced compared to mice that are infected by subcutaneous infection in the midline of the back.²¹

ANTIBODY RESPONSES

Prior to the development of an antibody-specific immune response, the degree of clearance by circulating phagocytes is very limited, indicating that the humoral response to *B. burgdorferi* might be necessary for resolution of spirochetal infection. In addition to usual T-cell-dependent antibody responses to *B. burgdorferi*, T-cell-independent humoral responses also confer protection to the host. Furthermore, T-cell-independent humoral immune responses are critical for resolving symptoms associated with *B. burgdorferi* infection. T-cell-deficient mice infected with *B. burgdorferi* mount a protective antibody response, which upon passive serum transfer affords protection to severe combined immune deficiency (SCID) mice from homologous challenge. However, mice that lack both B and T cells developed severe arthritis and carditis in response to infection with *B. burgdorferi*.

Stimulation of CD40L, which interacts with CD40 on T cells, is crucial for T-cell-dependent activation of B cells and subsequent antibody production. Mice deficient for CD40L are also able to generate protective antibody responses against *B. burgdorferi* and therefore resolve infection.²² Additionally, class II MHC-deficient mice are able to resolve symptoms associated with *B. burgdorferi* infection.²³ Thus, it is implied that *B. burgdorferi* antigens have the ability to stimulate B cells to expand clonally and differentiate into antibody-producing plasma cells, and that T-cell-independent humoral responses are extremely important for the protective immunity against *B. burgdorferi*.

The importance of antibodies in controlling *B. burgdorferi* infection was underscored by the discovery of complement-independent bactericidal antibodies, which have the capacity to control an infection. An IgG1 κ monoclonal antibody termed CB2 binds to *B. burgdorferi*-OspB via a single lysine residue, causing an alteration in the structure of OspB, thereby, increasing its susceptibility to protease degradation, and ultimately leading

to the lysis of the spirochete.²⁴ Another bactericidal antibody, H6831, with identical specificity to OspB was reported. Both CB2 and H6831 are so effective at killing *B. burgdorferi* that their selective pressure on the growth of *B. burgdorferi* was used to generate escape mutants of *B. burgdorferi* that lacked the lysine necessary for antibody binding to OspB, which made the escape mutants less infectious.

MECHANISMS OF IMMUNE EVASION

B. burgdorferi has evolved sophisticated mechanisms for immune evasion, which is not surprising considering that this pathogen is able to establish chronic infection in the midst of a very strong immune response. Just as *B. burgdorferi* has evolved mechanisms to evade the host innate immune system, this organism has also evolved the ability to escape killing by the acquired immune system. It has long been speculated that microbes can acquire host antigens and avoid immune recognition. In addition to evading the effector mechanisms of the innate immune response, *B. burgdorferi* is able to evade the humoral response by interacting with the extracellular matrix of the mammalian host via attachment to decorin, a major component of the extracellular matrix. *B. burgdorferi* attaches to decorin with a ligand-binding lipoprotein known as decorin-binding protein A (DbpA). A deficiency in decorin reduces the incidence of Lyme arthritis in mice, suggesting that the interaction of DbpA with the extracellular matrix provides a protective niche for *B. burgdorferi*, and thus prevents humoral-mediated bacterial killing.

Another method used by members of the *Borrelia* genus to avoid clearance by the host immune system is antigenic diversity. The recurrent spirochetemia characteristic of relapsing fever is attributed to the antigenic diversity of relapsing-fever spirochetes, with each wave of spirochetemia resulting from the generation of new outer-membrane antigens not yet recognized by the host immune system. Spirochetes of a different serotype are generated by genetic rearrangement of silent variable major protein (VMP) encoding regions into an expression locus. *B. burgdorferi* differentially expresses outer-membrane antigens under pressure from the immune response, which might contribute to the spirochetes' ability to persist in the host. A mechanism that is potentially essential for spirochetal immune escape is the recombination that takes place at the *vls* locus,²⁰ which consists on a *vls* expression site (*vlsE*) located near the right telomere of the linear plasmid lp28-1 and 15 silent cassettes upstream. *vlsE* encodes a surface-exposed, immunogenic protein of 34 kDa.

Ticks of the *Ixodes* complex secrete a 15-kDa salivary protein known as Salp15 during engorgement. This protein binds to CD4 and inhibits the activation CD4 effector T cells. Presumably this immunosuppressive effect is beneficial for the tick as it enables the tick to engorge on the host long enough to receive an adequate blood meal. Interestingly, *B. burgdorferi* usurps Salp15 to facilitate its own transmission from the arthropod vector to the mammalian host. *In vivo* and *in vitro* adherence of Salp15 to *B. burgdorferi* through an interaction with OspC protects the spirochete from antibody-mediated killing,²⁵ increasing the pathogens' capacity to infect and colonize the mammalian host upon tick feeding.

IMMUNE RESPONSE AGAINST *TREPONEMA PALLIDUM*

The agent of syphilis is an extremely elusive microbe both to our immune system and to the researchers attempting to grasp the pathogenic mechanisms of this organism. For more than 500 years, syphilis

KEY CONCEPTS

PROTECTIVE VERSUS PATHOLOGICAL RESPONSES TO *TREPONEMA PALLIDUM*

- >> The role of the early innate response to *T. pallidum* is mysterious because immunogenic cell surface proteins able to activate pattern recognition receptors remain to be found
- >> It is likely that the cell-mediated immune response to *T. pallidum* is involved in the development of pathology following infection with the spirochete. Likewise, this response seems to be involved in the resolution of infection with *T. pallidum*
- >> The protection that the humoral response affords to the host is unclear. Furthermore, no definite antigens have been isolated from the spirochete, due to the inability to cultivate this organism *in vitro*

has been a recognized disease; however, due to the inability to culture these organisms *in vitro*, we have yet to elucidate many of the mechanisms by which this treponeme causes disease. Moreover, the inability to infect mice reproducibly, for which many specific immunological reagents are available, with the pathogen has limited our ability to examine specific immune responses *in vivo*. Coupled with that is the fact that our immune system is unable to recognize and successfully eliminate infection with this spirochete, resulting in persistent infections that have lasting health and social consequences. Our understanding of the immune responses to this pathogen is not nearly as detailed as our knowledge of those elicited in response to infection with *B. burgdorferi*.

Early studies showed that cell-mediated immunity had a protective role in response to infection with *T. pallidum*, which led researchers to believe that pathogenesis was a consequence of diminished cell-mediated immunity. However, more recent studies have cast doubt on this hypothesis. In genital ulcers (chancres) the immune cell population consists mostly of CD4 T cells and macrophages, and Th1 cytokines predominate in lesions of both primary and secondary syphilis.^{26,27} Furthermore, the cell-mediated immune response to *T. pallidum* correlates well with the resolution of primary and secondary syphilis.

Currently, the role of CD4 T cells in pathology resulting from infection with *T. pallidum* is still not fully understood. It is likely that the cell-mediated immune response to *T. pallidum* has a role in the manifestation of disease during infection with this spirochete, as indicated by the propensity of this organism to cause inflammatory disease. However, a dichotomy exists between the roles of the cell-mediated immune response to *T. pallidum*, in that development of pathology versus the resolution of infection are not mutually exclusive. For instance, it has been shown that an exaggerated cell-mediated immune response is involved in the manifestation of gummatous disease, which is a characteristic of tertiary syphilis.²⁸ Therefore, although the importance of a strong cell-mediated immune response to *T. pallidum* has been shown, the role that this specific immune response plays in the pathogenicity of the spirochete remains unclear.

Infection with *T. pallidum* invokes a humoral immune response early in the course of infection, which strengthens as the number of recognizable antigens increases during the progression of infection. A polymorphic gene family of *T. pallidum*, called *T. pallidum* repeat (*tpr*), has

recently been identified and shown to be related to the major surface protein (Msp) genes of *T. denticola*.²⁹ It has been shown that a single member of the *tpr* family, *tprK*, serves as an antigen for opsonizing antibodies, which suggests that this protein is a surface antigen of *T. pallidum*. However, there are only indications that surface antigens of *T. pallidum* exist. So, although candidate *T. pallidum* surface proteins have been advanced on the basis of porin activity or homology with a surface protein of *T. denticola*, there is no real evidence identifying specific surface antigens on *T. pallidum*. Furthermore, like most pathogenic organisms, *T. pallidum* has evolved various mechanisms to escape host killing. *T. pallidum* repeat protein K (TprK) is an immunogen with seven discrete variable regions differing among different isolates of the spirochete.²⁹ In fact, the antibody response to *T. pallidum* is directed against these variable regions, leading to the hypothesis that the antigenic diversity of TprK is involved in the reinfection of hosts despite robust immune responses.²⁹

Molecular, biochemical, and ultrastructural data have indicated that this spirochete possesses a molecular architecture responsible for its remarkable ability to evade the immune response,^{28,30} and, because of this, *T. pallidum* has been termed a stealth pathogen. The outer membrane of *T. pallidum* is comprised of mostly nonimmunogenic transmembrane proteins, and the highly immunogenic lipoproteins are contained within the periplasmic space.³¹ Therefore, this rare molecular architecture is thought to explain the poor antigenicity of living treponemes and its unique ability to evade killing by the host immune system.

CONCLUSION

Spirochetes are a phylogenetically ancient and distinct group of microorganisms. Because of their propensity to cause diseases in humans, *B. burgdorferi* and *T. pallidum* are the two best-studied spirochetes. However, the inability to culture *T. pallidum in vitro* has made researching this spirochete very difficult, and as a consequence our understanding of the immune response following infection with this spirochete is more limited.

The etiologic agents of Lyme disease and syphilis are similar in having relatively small genomes, surviving only in association with a host and eliciting inflammatory disease, but genomic comparison clearly shows that *T. pallidum* and *B. burgdorferi* are not closely related. It seems likely that these spirochetes evolved independently from a more complex ancestor, resulting in differences in their lifecycles, environmental adaptations, and the pathology associated with their infection, despite some similarities. Therefore, it is not surprising to learn of differences in the host immune response to *B. burgdorferi* and *T. pallidum*. Both the host response to these spirochetes and the infectivity of the bacterium determine the extent of pathology following infection.

Immune responses to viruses

Scott N. Mueller, Barry T. Rouse

27

Viruses as obligate intracellular parasites require their host to replicate them and to facilitate their spread to others. In humans, viral infections are rarely lethal, even if they are highly cytolytic to individual cells. Mortality commonly occurs when viruses jump species (such as Ebola or human immunodeficiency virus (HIV)), when the virus undergoes a major antigenic change (i.e., influenza viruses), or when host immunity is compromised. HIV represents one of the most dramatic human examples of an exotic virus that kills its host. However, HIV kills slowly, providing ample time to spread to new hosts and an effective strategy for persistence in the species. Death or dire consequences following virus infection in mammals with inadequate immunity are well illustrated by observations that fetuses or neonates, especially if deprived of passive immunity, succumb to many agents well tolerated by normal adults. The increasing wealth of immunological tools, such as transgenic animal models and major histocompatibility complex (MHC) tetramers, have provided sensitive methods for defining the relevance of immune mechanisms for antiviral defense. In most situations, defense against viruses involves multiple immune components, and the impact of a single mechanism varies greatly according to the method by which individual viruses enter, replicate, and spread within the host. In this chapter, we highlight the principal means by which the host achieves immunity following infection by viruses. Table 27.1 presents an overview.

VIRAL ENTRY AND INFECTION

Access to target tissues presents numerous obstacles for entry and infection by most human viruses. Most effective of these are the mechanical barriers provided by the skin and mucosal surfaces, as well as the chemically hostile environment of the gut (Fig. 27.1). A number of common human viral pathogens enter through the gastrointestinal tract, including rotavirus, enteric adenoviruses, and hepatitis A virus (HAV). These are usually spread via person-to-person contact or contaminated food and water. Respiratory infections caused by influenza viruses, rhinoviruses, coronaviruses, measles virus, varicella-zoster virus (VZV), and respiratory syncytial

virus (RSV) are often spread by aerosol transmission, as well as person-to-person contact. Many of the herpes viruses target the skin or the mucosae, such as herpes simplex virus (HSV) and VZV. HSV in particular can infect oral and genital mucosa, the eye, and the skin through small cuts and abrasions. Other herpes viruses, such as Epstein-Barr virus (EBV) and cytomegalovirus (CMV), target the mucosa. CMV can also spread vertically from mother to baby or rarely via blood transfusions. Human papillomavirus (HPV) targets skin and mucosa and causes warts and may transform cells, inducing cancers such as cervical cancer. Viruses such as West Nile virus and Semliki forest virus may also enter through the skin via insect vectors. HIV and hepatitis B virus (HBV) are commonly spread via sexual contact. HIV, HBV, and hepatitis C virus (HCV) can also infect humans via direct entry into the bloodstream via transfusions or contaminated needles.

Most human viruses replicate only in certain target tissues, this being mainly the consequence of viral receptor distribution. Many viruses use two receptors, such as the use of the CD4 co-receptor and CCR5 by HIV. After attachment to a cellular receptor, viruses may fuse with the cell membrane or be endocytosed and then gain entry into the cytoplasm or nucleus by fusing with the vesicular membrane (enveloped viruses such as HSV and HIV), or translocate across the cell membrane or induce lysis of the endocytic vesicle once in the cytoplasm (nonenveloped viruses such as Norwalk virus and poliovirus).¹ Viruses then utilize host cell machinery and specialized virally encoded proteins to replicate rapidly within the cell. Once they have multiplied within the cell, many viruses induce cytolysis in order to facilitate release of new infectious virions (the poxviruses, poliovirus, and herpes viruses, for example). Other viruses are released from infected cells by budding through the cell membrane in the absence of cell death (i.e., HIV and influenza virus). Having entered the body, however, viruses encounter numerous innate defenses and activate the components of adaptive immunity. The latter usually assures that clinical disease, if not infection, will not become evident. Successful exploitation of these defenses through the use of vaccines remains a central challenge for many human viruses, particularly those that cause chronic infections such as HIV and HCV.²

Table 27.1 Viral infections and immunity

Viral event	Obstacles	Time course
Transmission	Mechanical and chemical barriers	0
Infection and replication	Innate immunity	0 →
Infection stopped or spreads	Viral antigens transported to lymphoid tissues	Within 24 hours
Infection controlled	Specific antibodies and cell-mediated immunity	4–10 days
Sterile immunity	Immune memory	14 days to years
Viral persistence if infection not controlled	Immune disruption or evasion	Weeks to years

Fig. 27.1 Common routes of entry and infection for human viral pathogens. CMV, cytomegalovirus; HBV, hepatitis B virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

INNATE IMMUNITY TO VIRUSES

Viral infection induces an extensive array of defense mechanisms in the host. Innate defenses come into play to block or inhibit initial infection, to protect cells from infection, or to eliminate virus-infected cells, and occur well before the onset of adaptive immunity (Chapter 3). The innate immune defenses are initiated via pathogen recognition receptors of the Toll-like receptor (TLR) family or a family of DExD/H box RNA helicases (Table 27.2).³ These cellular sensors promote the expression of type I (α/β) interferons (IFN) and a variety of IFN-stimulated genes and inflammatory cytokines.⁴ TLRs are cell surface or endosomal membrane-bound proteins expressed by numerous cells including dendritic cells (DC), macrophages, lymphocytes, and parenchymal cells.⁵ Expression of TLRs is largely inducible in most cell types, though some (TLR7/8/9) are constitutively expressed at high levels by specialized plasmacytoid DC for rapid IFN production. Different TLR molecules recognize specific viral products such as single- and double-stranded RNA (TLR 3 and TLR7/8, respectively) or double-stranded DNA (TLR9). The more recently described non-TLR RNA helicases, retinoic acid-inducible gene

I (RIG-I) and melanoma differentiation-associated gene (MDA-5), mediate cytoplasmic recognition of viruses.⁶ It is thought that other cytoplasmic sensors of viruses are also likely to exist such as the recently discovered cytosolic dsDNA sensor DAI (DNA-dependent activator of IFN).

The innate defense system consists of multiple cellular components and many specialized proteins. The longest-known and best-studied antiviral proteins are the α/β IFNs, which act by binding to the type I IFN receptor and result in the transcription of more than 100 IFN-stimulated genes. One consequence of this 'antiviral state' is the inhibition of cell protein synthesis and the prevention of viral replication. Type I IFNs also activate natural killer (NK) cells and induce other cytokines such as interleukin (IL)-12 that promote NK responses. NK cells produce proinflammatory

cytokines, they can kill infected cells and interact with DC, and are an important component of innate defense against viruses (Chapter 18). NK cells are regulated by an array of activating and inhibitory receptors whose expression and function are just beginning to be understood.⁷ Uninfected cells are usually protected from NK cell cytotoxicity as they deliver negative signals such as high expression of MHC molecules. In contrast, virus-infected cells are killed either because they deliver positive signals or because they lack adequate MHC-negative signals. The NK defense system appears important against some herpes viruses, which downregulate MHC expression in the cells they infect. NK cells are also important in resistance to mouse and human cytomegalovirus, and possibly to HIV, influenza virus, and Ebola viruses.⁸ A distinct NK cell population, NKT cells, may provide some antigen-specific innate immune protection against certain viruses. Many other leukocytes are involved in innate defense, including macrophages, DC, neutrophils and perhaps T cells expressing $\gamma\delta$ T-cell receptors for antigen (Chapter 3).

KEY CONCEPTS

PRINCIPLES OF ANTIVIRAL IMMUNITY

- >> Many human viral infections are successfully controlled by the immune system
- >> Certain emerging viruses may overwhelm the immune system and cause severe morbidity and mortality
- >> Other viruses have developed mechanisms to overwhelm or evade the immune system and persist
- >> Individuals with defects in innate or adaptive immunity demonstrate more severe viral infections
- >> T-cell immunity is more important for control than antibody with many viral infections
- >> Antibody is important to minimize reinfection, particularly at mucosal sites
- >> Immune memory is often sufficient to prevent secondary disease, though not in all viral infections

In addition to IFN- α/β , several other host proteins function in antiviral defense. These include natural antibody, which may play a role in defense against some virus infections, as well as the complement proteins (Chapter 20). Some viruses may be directly inactivated by complement activation or be destroyed by phagocytic cells that bind and ingest complement-bound virions. Several cytokines and chemokines induced by virus infection also play a role in defense. These include the cytokines TNF- α , IFN- γ , IL-12, IL-6, and chemokines such as MIP-1 α . In particular, IL-12 is a potent inducer of IFN- γ from NK cells (Chapter 10). Inflammatory chemokines may also play an important role in innate antiviral defense by orchestrating macrophage, neutrophil, DC, and NK responses at the site of infection⁹ (Chapter 11). Not only are these components of innate immunity involved in mediating initial protection against viruses, several components (such as the TLRs and type I IFN and IL-12) serve to shape the nature and effectiveness of the subsequent adaptive response to viral antigens.

ADAPTIVE IMMUNITY TO VIRUSES

Innate immunity generally serves to slow, rather than stop, viral infection, allowing time for the adaptive immune response to begin. The two major divisions of adaptive immunity, antibody and T-cell-mediated, are mainly directed at different targets. Antibodies usually function by binding to free viral particles, and in so doing block infection of the host cell. In contrast, T cells act principally by recognizing and destroying virus-infected cells. As all viruses replicate within cells and many of them spread directly between cells without re-entering the extracellular environment, resolution of infection is reliant more on T-cell function than on antibody. Antiviral antibody, however, does assume considerably more importance as an additional immunoprotective barrier against

reinfection. It is the presence of antibody at portals of entry – most often mucosal surfaces – that is of particular relevance to influenza and HIV infections. Accordingly, vaccinologists try to design vaccines that optimally induce mucosal antibody.

Initiation of adaptive immunity is closely dependent upon early innate mechanisms that activate antigen-presenting cells (APC). APC and lymphocytes are drawn into lymphoid tissues by chemokine and cytokine signals and retained there for a few days in order to facilitate effective interactions between these cells. The architecture of the secondary lymphoid tissues supports the coordinated interactions between cells of the adaptive immune system through a network of supportive stromal cells and local chemokine gradients.¹⁰ The induction events occur in lymph nodes draining the infection site, or in the spleen if virus enters the bloodstream. The passage of viral antigens to lymph nodes usually occurs in DCs. Some viruses are able to compromise the function of APC, such as HSV and measles virus, which can inhibit DC maturation.

B-cell activation occurs following antigen encounter in the B-cell follicles, and possibly the T-cell zones, in the spleen or lymph nodes¹¹ (Chapter 2). Some activated B cells become short-lived plasma cells while others move the edges of the B-cell follicles and interact with antigen-specific helper CD4 T cells via presentation of antigenic peptides on B-cell MHC class II molecules. These activated B cells initiate germinal center (GC) reactions, which ensure somatic hypermutation and affinity maturation for the selection of high-affinity, antibody-producing long-lived plasma cells as well as memory B cells¹² (Chapter 8). Recent advances have greatly improved our understanding of the signals that control the generation of these important B-cell subsets, particularly at the molecular level.¹³ We now know that upregulation of the transcription factors Blimp-1, XBP-1, and IRF-4 dictates plasma cell formation, whereas Pax-5 expression delineates B cells destined for GC reactions and the memory B-cell lineage.

Antibody binding to epitopes expressed by native proteins at the surface of free virions usually blocks viral attachment or penetration of target cells. Sometimes the consequence is viral lysis (with complement proteins also involved), opsonization, or sensitization for destruction by Fc receptor-bearing cells that mediate antibody-dependent cellular cytotoxicity (ADCC). Occasionally, however, Fc receptor binding of antibody-bound virus may facilitate infection and result in more severe tissue damage. This occurs in dengue fever and may happen in some instances in HIV infection.¹⁴

As indicated previously, antibody may function most effectively to prevent reinfection, especially at mucosal surfaces. The antibody involved in humans is predominantly secretory immunoglobulin A (IgA), but serum-derived IgG may also be protective, particularly in sites such as the vaginal mucosa.¹⁵ Both antibody isotypes act mainly to block infection of epithelial cells, although in some instances the antibody may transport antigen from within the body across epithelial cells to the outside. Mucosal antibody persists for a much shorter period than does serum antibody, which explains in part why immunity to mucosal pathogens is usually of much shorter duration than is immunity to systemic virus infections.

Like B-cell responses, T-cell responses to viral infections also begin within the lymphoid tissues. Specific CD8 cytotoxic T lymphocyte (CTL) precursors recognize antigen in the context of MHC class I-peptide antigen complexes on professional APC, such as DC. The CD8 T cells become activated, proliferate, and differentiate into effectors. Expansion of these naïve antigen-specific precursors is considerable, often exceeding 10 000-fold, and results in an effector population that

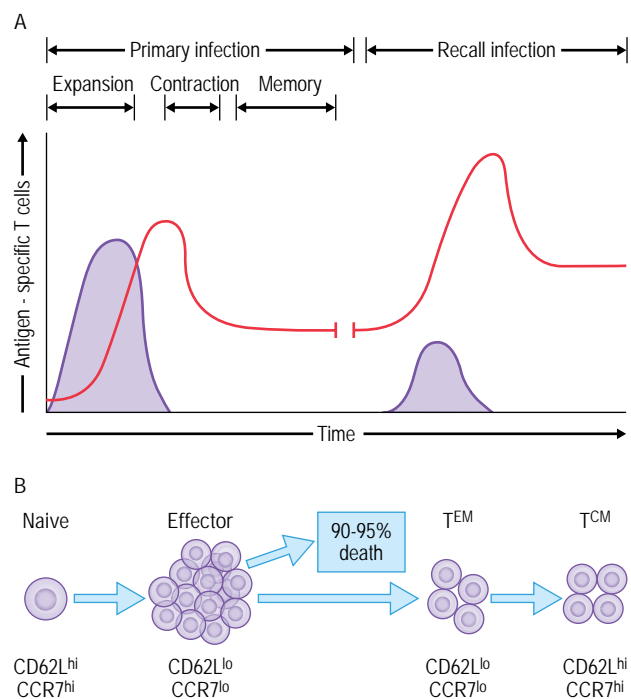

Fig. 27.2 Expansion/contraction/memory phases of adaptive immunity and memory cell subsets. (A) Dynamics of primary and secondary (recall) T-cell responses to viral infection. Both primary and recall T-cell responses undergo expansion and contraction phases, followed by stable immune memory. Recall responses induce a larger effector pool and reduced contraction further boosting the memory pool. (B) Effector and memory T-cell differentiation. Antigen stimulation expands effector cells, most of which die during the contraction phase. T_{EM} cells that are formed gradually convert to T_{CM} cells over time, with corresponding changes in surface marker expression.

can account for 40% or more of a host's total CD8 T-cell population (Fig. 27.2). Various factors, including antigen and APC, co-stimulatory molecules (such as CD28 and 4-1BB) and inflammatory cytokines (such as IFN- α/β and IL-12) are required to program the development of functional effector lymphocytes.¹⁶ The CTL effectors enter the efferent lymph and bloodstream and access almost all body locations, including both primary and subsequent sites of infection. However, effectors do not stay activated for long once the virus is cleared, and approximately 95% die by a process termed activation-induced cell death. Following this contraction phase, the remaining cells differentiate into memory cells, which remain as a more or less stable population in the host for many years. They represent an expanded pool of CTL precursors that can be activated upon secondary encounter with antigen, and provide enhanced protection upon reinfection with the same virus. The topic of memory and homeostasis as it relates to antiviral immunity is further discussed later in this chapter.

T-cell immunity against a particular virus commonly involves both CD4 and CD8 T-cell subsets. Both CD4 and CD8 T cells recognize peptides derived from viral antigens bound to surface MHC proteins

KEY CONCEPTS

ANTIVIRAL T- AND B-CELL IMMUNITY

Effector systems	Recognized molecules	Control mechanisms
Antibody	Surface proteins or virions	Neutralization of virus, opsonization, or destruction of infected cells by ADCC
Antibody + complement	Surface proteins expressed on infected cells	Infected cell destruction by ADCC or complement-mediated lysis
Mucosal antibody (IgA)	Surface proteins or virions	Viral neutralization, opsonization, and transcytosis
CD4 T cells	Viral peptides (10–20 mers) presented on MHC class II – surface, internal or nonstructural proteins presented by APC	Antiviral cytokine and chemokine production; help for CD8 T-cell and B-cell responses; killing infected cells; regulatory functions to reduce immunopathology
CD8 T cells	Viral peptides (8–10 mers) presented on MHC class I – surface, internal or nonstructural proteins presented on infected cells or by cross-presentation	Killing infected cells or purging virus without cell death; antiviral cytokine and chemokine production

ADCC, antibody-dependent cellular cytotoxicity; APC, antigen-presenting cell; IgA, immunoglobulin A; MHC, major histocompatibility complex.

(class II and class I, respectively). Complexes of viral peptides bound to MHC class II proteins are generated by APC from scavenged and processed virus-infected cells or viral particles. Antigen–MHC class I complexes are expressed on the surface of infected cells, and antigen can also be transferred to APC from infected cells by a process known as cross-priming.¹⁷ Recent experiments in mice have also demonstrated a role for transfer of antigen between DC¹⁸ as they migrate from infected tissues to the lymphoid tissues. Curiously, although many peptides derived from viral proteins have an appropriate motif that permits MHC binding, the majority of CD8 T cells, and possibly CD4 T cells, are often specific for a few immunodominant epitopes.¹⁹

During the past few years there have been major advances in the techniques to quantify antigen-specific T-cell responses. The most revolutionary of these has been the use of MHC class I and class II tetramers to directly visualize antigen-specific CD8 and CD4 T-cell responses, respectively.²⁰ Many recent studies have used MHC class I tetramers to analyze virus-specific CD8 T-cell responses both in animal models and in humans. These studies demonstrated the significant size of CD8 T-cell responses to viruses and that the majority of the activated CD8 T cells seen at the peak of the response are virus-specific.

CTL function by recognizing virus-infected cells and killing them (Chapter 18). This often involves perforins and cytotoxic granules containing granzymes. Effector CTL can also induce death in target cells following engagement of Fas ligand on the CTL with Fas on target cells. Both pathways lead to apoptosis of the target cell, involving the degradation of nucleic acids, including those of the virus. Alternatively, CD8 T cells also mediate defense through the release of various cytokines following antigen recognition. Some of the cytokines and chemokines most highly produced by CTL include IFN- γ , TNF- α , lymphotoxin- α , and RANTES (Chapters 10 and 11). These cytokines can have multiple antiviral effects on infected cells and the cells around them, including purging of virus from infected cells without killing the

cell. This is particularly important for viruses like HSV which infects nonrejuvenating cells such as nerve cells.

CD4 T cells are also involved in antiviral defense. They are important, though not always essential, for controlling infections such as HSV, influenza virus, HIV, and many others. CD4 T cells participate in antiviral immunity in several ways. First, the subset acts as helper cells for the induction of both antiviral antibodies and CD8 T-cell responses to most virus antigens.^{11, 21} CD4 T cells also function as antiviral effector cells, and generate stable memory cell populations similar to those of CD8 T cells.²² The differentiation of CD4 T cells into effectors occurs in a manner very similar to that with CD8 T cells. At present less is known about the size and specificity of CD4 T-cell responses, but reports indicate that CD4 T cells undergo less expansion during virus infections, resulting in an effector pool smaller than that observed with CD8 T cells. CD4 T cells are activated by recognizing viral peptides. However, these are larger than those involved in CD8 T-cell recognition and are associated with class II MHC molecules present on more specialized cells such as APC (Chapter 6). Thus, CD4 T cells rarely recognize viral epitopes present on cells as a consequence of viral gene expression within that cell, dictating their function as helper cells for B cells and CD8 T cells, and as producers of cytokines for help and viral clearance.

In some instances CD4 T cells can perform cytotoxic functions, though not as effectively as CD8 CTL. More commonly, however, effector CD4 T cells act by synthesizing and releasing numerous cytokines following their reaction with antigen (Chapter 17). Subsets of CD4 T effectors produce different groups of cytokines. The type most often involved in antiviral defense are designated T-helper 1 (Th1) cells, and primarily produce IFN- γ , LT α , TNF- α , and IL-2 to help orchestrate the inflammatory response and act directly or indirectly in antiviral defense. Conversely, Th2 effectors produce an array of cytokines that may downregulate the protective function of Th1 cells, such as IL-4, IL-5, and two anti-inflammatory cytokines, IL-10 and transforming

growth factor- β (TGF- β). Th2 T cells play a protective function against some parasite infections (Chapter 29), though in some virus infections an exuberant Th2 response may be associated with immunopathology or impaired immunity. Indeed, blocking the Th2 cytokine IL-10 was recently shown to assist in the clearance of chronic viral infection. Additionally, an IL-17-producing subset of effector CD4 T cells has also been described (Th17), with potential roles in immune pathogenesis.²³

IMMUNOLOGICAL MEMORY

Immunological memory is a cardinal feature of adaptive immunity. The goal of vaccinology is to induce long-lived immunological memory to protect against reinfection. Following infection with certain viruses, memory can be exceptionally long-lived, potentially for the life of the host (i.e., measles and smallpox viruses).^{24,25} It is now understood that memory is defined by the persistence of specific lymphocytes and antibody-producing plasma cells, rather than persisting antigen inducing continuous lymphocyte activation. Humoral memory to viruses involves long-lived plasma cells in the bone marrow that provide a continuous low-level source of serum antibody.²⁶ This maintenance of humoral immunity also involves a population of homeostatically maintained memory B cells. However, the precise relationship between memory B cells and long-lived plasma cells in maintaining humoral immunity is uncertain. The pool of memory T cells is regulated by low-level homeostatic division controlled by the cytokines IL-7 and IL-15. For memory CD8 T cells, IL-7 is primarily important for survival while IL-15 is crucial for low-level proliferation to maintain the size of the memory T-cell pool.²⁷

Immunological memory is defined by a pool of antigen-specific cells whose increased frequency enables rapid control of viral reinfection (Fig. 27.2).²⁸ Recent studies identified a population of IL-7 receptor- α -expressing effector cells as the precursors of this memory pool.²⁹ This population of cells, which constitutes ~5–10% of the effector pool, preferentially survives the contraction phase, and gradually differentiates into a stable memory population. Upon reinfection, these memory cells can be rapidly activated, and by virtue of their increased frequency mediate more rapid clearance of the viral pathogen. Moreover, repeated stimulation of memory cells via multiple infections with the same virus, or prime-boost vaccine regimes, further increases the size of the antigen-specific memory T-cell pool.³⁰ Re-stimulation also affects the activation status and tissue distribution of memory T cells, which may enhance protection from viral infection in mucosal, and other, tissues.

Experiments in humans and mice have demonstrated that memory T cells are heterogeneous. Memory T cells have been divided into effector memory (T_{EM}) and central memory (T_{CM}) subsets, defined by expression of two surface molecules involved in T-cell migration: CD62L and CCR7.³¹ The CD62L^{lo}CCR7^{lo} T_{EM} subset is found primarily in non-lymphoid tissues and spleen, whereas the CD62L^{hi}CCR7^{hi} T_{CM} subset are largely present in the lymph nodes and spleen. The current model predicts that effector T cells form the T_{EM} subset; these cells gradually convert to a T_{CM} phenotype over time. Though the conditions that control the rate of this conversion are unknown, it is likely that the amount of antigen and inflammatory signals received during the effector phase greatly influences this. It has also been shown that CD4 T-cell help is

required for the generation of long-lived memory CD8 T cells; however, exactly when this help is required during the differentiation of effector and memory T cells is uncertain.²¹

Recent studies have suggested that T_{CM} are capable of mounting stronger proliferative responses following reinfection. However, the tissue-specific homing of T_{EM} cells permits them to reside in sites of potential viral infection, such as the skin and mucosae. These differences may define the physiological *raison d'être* for these two memory T-cell subsets. Indeed, protection from localized viral infections such as HSV-1, influenza, and vaccinia virus in mice is more dependent upon T_{EM} cells.^{32–34} However, studies suggest that memory in peripheral tissues may be less effective, or wane over time. This appears to be the case in the respiratory tract,³² explaining in part why vaccines against respiratory viruses have a poor record.

IMMUNE EVASION AND IMMUNITY TO CHRONIC VIRAL INFECTIONS
